Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e" if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963–65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings to be in Indian ink on heavy cartridge paper, tracing paper or similar materials: thin, shiny, torn or folded material should be avoided. Scales for graphs should be chosen such that simple figures will not occupy an inordinate amount of space. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text they should contain only essential material. Ideally, an unlabelled original and a labelled copy should be provided: labelling on photographs should, if possible, be avoided entirely. Records, charts etc. which will not reproduce well should be redrawn or simply described in the text. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

MERCK SHARP AND DOHME RESEARCH LABORATORIES
SCIENTIFIC LECTURE 1976
FLEXIBLE DRUG MOLECULES AND DYNAMIC RECEPTORS

by PROFESSOR R. J. P. WILLIAMS, F.R.S.

Wadham College and the Inorganic Chemistry Laboratory, Oxford

The lecture will be presented at the Royal College of Physicians, London, on Wednesday, 20th October 1976, at 5 p.m. (Tea and biscuits will be served from 4 p.m.). Invitations are now being sent and may be obtained by completing the application form.

To: Dr. W. G. Thomas,
    Merck Sharp & Dohme Research Laboratories,
    Hertford Road, Hoddesdon, Herts., EN11 9BU

For the 1976 lecture, please send an invitation to:

Two members of *Nature's* staff leave early in October.

Roger Woodham, Deputy Editor, is being promoted to Publishing Manager of Macmillan Journals Ltd. He has been with *Nature* for six years, during which time he has turned his hand to almost everything in the journal, but most recently to the physical science manuscripts and to maintaining the quality of production.

Allan Piper is leaving to become a writer with *The Oilman*. He has been with *Nature* for three years during which he has been a sub-editor, book-reviews editor and, for the last year, Assistant News Editor.

Ready for rapid separation

Pharmacia prepacked, disposable Columns PD-2 and PD-10. Prepacked with Sephadex G-25 Medium for maximum economy and convenience in routine laboratory use.

Columns PD-2
Bed volume, 1.5ml

Suggested applications include: analysis for total serum thyroxine, analysis for serum triiodothyronine, removal of excess reagents from labelled proteins and removal of interfering ions before enzyme determinations.

Columns PD-10
Bed volume, 9.1ml

Desalting and buffer exchange with sample volumes of up to 2.5 ml in less than five minutes.

Pharmacia
Fine Chemicals

Genetic guidelines: handle with care

PERFECT democracy or perfect dictatorship? That is a question which might well have to be asked now that the *Report of the Working Party on the Practice of Genetic Manipulation* has been published (Cmnd 6600, HMSO, 50p). Its recommendations embody a principle that Britain already knows in respect of its pay policy: that, threatened by a legislative hammer, everyone 'voluntarily' acquiesces in publicly announced guidelines.

The working party divides experiments into four categories (depending on their hazards) and provides a code of practice to cover each category (for details, see page 4). Researchers will submit details of their experiments to a Genetic Manipulation Advisory Group (GMAG), which will vet and categorise the work. They can then decide voluntarily whether or not to abide by the advice of the GMAG and to follow the code of practice.

But at the same time, details of the experiments will have to be submitted to the Health and Safety Commission (HSC), which has turned its eye specifically to all forms of genetic manipulation of micro-organisms, including those which preceded the advent of the new technology for recombinant DNA. The HSC will, through its inspectors, police the work using the existing (and very wide ranging) Health and Safety at Work Act, which it administers. The great advantage of this Act is that it applies to all employers, in industry, public laboratories and universities. This has allowed the working party to avoid the problem being faced in the United States, where guidelines control only research sponsored by the National Institute of Health (NIH) and leave industrial and defence-related work largely untouched.

So unspecific is the legislation, in fact, that it could probably cover any laboratory which carried out any experiment deemed to be hazardous to those who worked there. But, the HSC is now considering what special provisions it might need to give it more specific and authoritative control of genetic manipulation experiments. So the Act will be reinforced by a set of regulations, a draft of which has been produced. Their final form will depend on suggestions and recommendations received between now and November. One possibility is that the HSC will adopt the commendably detailed Code of Practice proposed by the working party, thus giving it a basis in law.

The GMAG, which will produce an annual report, will clearly be a powerful body. To its credit the working party offers the GMAG flexibility by refusing to go into the kind of detailed categorisation of experiments produced by the NIH in its analogous regulations; the preference, plainly, is for learning by experience. In addition the working party has considered not just the medical hazards of genetic manipulation in isolation, but also the potential dangers to plant and animal populations, which are included within the GMAG's scope.

The members of the GMAG, which will be responsible to the Secretary of State for Education and Science, will be announced as soon as possible. The main problem is likely to be the initial bottleneck in dealing with the batch of proposed experiments, some of which have lain dormant for two years. The GMAG is going to have to work speedily to overcome its own inexperience and the growing impatience of those now being encouraged by the working party, who have postponed their most exciting experiments.

Even more, of a problem may face the biological safety officer, whom the working party recommends be appointed in every laboratory carrying out genetic manipulation experiments. His task, particularly in the higher-risk laboratories, would be as onerous as it is important. And in the event of any prosecution under the Health and Safety at Work Act, he could not necessarily pass the buck on to the head of department to whom he is responsible. Given this, and the disinclination of most people to control the work of their colleagues, the job of biological safety officer may not prove to be a popular one. Might there not be a case, particularly in those laboratories with a major interest in genetic manipulation, for the appointment of a suitably trained person to that specific and sole role?

There is one slightly worrying aspect about the way the proposals have emerged. It relates to the British distaste for debate in full public view. Thus far, it has certainly been possible to state a view and have it considered by those deliberating the issues—but there has been nothing like the openness afforded in the United States. Greater openness would have produced an equally satisfactory result, and perhaps as quickly. But it would have also have meant greater legitimacy for the final course of action. The effectiveness of the proposals will be a reflection of how well or badly British science manages itself.

Off the tobacco road

UK cigarette manufacturers have reached
a crucial stage in the development of
substitute tobacco. **Allan Piper** reports

CIGARETTES containing what have
become known as "supplements" could
be on the UK market within 6 to 9
months. Rigorous health trials, recom-
mended by the UK Independent Scien-
tific Committee on Smoking and
Health, should be completed soon, and
three major tobacco companies with
British interests—Carreras Rothmans,
Gallahers and Imperial Tobacco—are
then expected to submit their results to
the committee.

The committee is an advisory body to
the Department of Health and Social
Security (DHSS) set up in 1973 under
the chairmanship of the Vice-Chancellor
of Birmingham University, Dr R. B.
Hunter. If it is satisfied that the find-
ings meet the guidelines it laid down
last year, the committee is expected to
recommend the licensing of supple-
ments for immediate commercial
development in Britain.

One company won't be on the early
bandwagon. Courtaulds decided last
month to hold back on its development
of a tobacco substitute. The decision,
however, was merely the commercial
judgment of a company temporarily
sidestepping an area of heavy pioneer-
ing expenditure which is already
covered by the others in the field.
Once supplements have been broadly
sanctioned, of course, Courtaulds can
jump straight back into the arena,
reasonably certain that the £3 million,
which it needs to carry its own product,
Tabrelle, through the Hunter tests, is
unlikely to disappear down the drain
The company will be up to two years
behind those already through the trials.
But it can take this course because
Tabrelle is essentially similar to the
other products being tested by the
tobacco companies.

Two types

There are, in fact, only two basic
types of supplement. One is made up of
largely inorganic materials called inert
diluents, the other is based on organic
cellulose derivatives. Both use an
organic binder. On current medical
reckoning—that the cigarette cancer
risk stems directly from the tar con-
tent of smoke—both kinds of supple-
ment provide a safer alternative to
ordinary tobacco. Organically based
varieties, such as Tabrelle and the un-
imaginatively named NSM ('New
Smoking Material') give less than

40% of the amount of tar produced by
ordinary tobacco. With Cytrel, the
main inorganic variety, even that
reduction can be improved two-fold.
This relative advantage is reinforced
further because the organic NSM pro-
duces more carbon monoxide, alde-
hydes and so-called furam derivatives
than tobacco, perhaps posing an addi-
tional, though as yet undetermined,
health threat.

In the event, none of the major
tobacco companies in Britain has
plumped squarely for one type of
supplement rather than the other.
Gallahers is maintaining an equal
interest in both Cytrel and NSM. And
while Carreras Rothman and Imperial
Tobacco have moved more positively in
one particular direction, respectively
favouring Cytrel and NSM, both com-
panies have kept their eyes on the
alternative option.

These preferences have resulted in
close research links between the retail-
ing tobacco companies and the manu-
facturing chemical corporations.
Carreras Rothman have an arrange-
ment with Celanese, the US makers of
Cytrel, while the tie between Imperial
Tobacco and ICI has led to the forma-
tion of the joint consortium NSM Ltd,
planned as an eventual commercial
manufacturer and supplier. In Ger-
many, the chemical giant Bayer has
just terminated a liaison with
Reemstma, following the spectacular
failure there last year of two brands
containing supplements. As for co-
operation betwen the companies and
the Hunter Committee, this is coordi-
nated by the Tobacco Advisory Council
and has apparently been effective, in
spite of misgivings within the industry
about the Committee's strong academic
make-up.

Three stages

The Hunter guidelines separate tests
into three stages, with an interim
check at the end of Stage I. This first
stage, already passed safely, included
comprehensive studies of smoke chem-
istry, together with inhalation tests
using rats and monkeys over a period
of at least six weeks. Stage II involved
short-term clinical studies of respiratory
irritation in human volunteers. At this
stage the tobacco companies were also
free under the guidelines to conduct

controlled consumer trials to assess
such characteristics as flavour accept-
ability.

The third stage, now virtually com-
pleted, involves the most rigorous tests
of all. Studies at this level fall into
three categories: carcinogenicity trials,
which include the classic mouse skin-
painting test; reproduction and terato-
logical studies, designed to assess
possible side-effects of smoking supple-
ments; and, finally, life-long inhalation
studies on rats and other species, which
in Britain has already led to the con-
troversy over the use of baboons and
beagles.

In a world context the Hunter
guidelines are unique, and most
interested corporations outside Britain
hope that once their UK competitors
have borne the expense of breaking
new ground, Hunter Committee ap-
proval can be used to ward off future
criticism of supplements on respective
domestic fronts. The £3 million cost
for the tests carry total development
costs for the tobacco companies in
Britain to around £10 million each over
the past five or six years.

When the committee licences the
supplements, marketing will begin. For
historical tax reasons they are still
grouped with additives in the Finance
Act, but new legislation to bring them
under the Medicine Act is expected to
be through parliament within the first
couple of months of next year. Without
hitches, cigarettes containing up to 25%
supplement could thus be on the British
market by March 1977.

NSM Ltd already has a large pro-
duction plant ready at Ardeer in Scot-
land, a £14 million investment by
Imperial Tobacco. Reports indicate
that Courtaulds could have Tabrelle in
commercial production within a year of
the Hunter green light for an additional
investment of £10–20 million. And
from across the Atlantic, Celanese can
be expected to provide all the Cytrel
needed in the early stages of UK
marketing. Similar products such as the
Anglo-American Batflake and Bayer's
still mysterious blend can also be ex-
pected to emerge rapidly once they
have passed through the Hunter tests.

Failure to win licences at the first
attempt would mean a major setback,
but the search for a safer cigarette will
certainly not be abandoned, even
though supplements are by no means
universally accepted as the most effec-
tive way to reduce the smoking risk.
Improvements to existing filters, parti-
cularly through ventilation, offer
another possibility, as does an increased
porosity of cigarette papers. The search
meanwhile continues for that elusive
premium blend of tobacco which gives
maximum possible taste with minimum
possible tar. ☐

The OTA on the EPA

Wil Lepkowski looks at the US Environmental
Protection Agency, the subject of a recent report.

WHEN the Environmental Protection
Agency was formed in late 1970, one
of the justifications for its creation was
that a single agency could take better
responsibility for restoring environ-
mental quality than a group of
separate fiefdoms. EPA, the argument
went, would view the environment as
a single, interrelated whole through an
administrative structure that was itself
correspondingly integrated. Environ-
mentally conscious America heaved a
sigh of assurance that at last the quality
of life and the preservation of Space-
ship Earth were given the policy
enthronement they merited.

While the human cell may be the
perfect blending of structure and func-
tion, EPA decidedly is not. It has faced
many reorganisations of its research
and development branches, internal
controversies, budgetary disappoint-
ments and manpower freezes; it has
suffered from conflicting Congressional
mandates, court setbacks to its enforce-
ment decisions, political shoving mat-
ches, and has had its programmes
skewered by new energy policies. Little
wonder, then, that EPA continues to
find the exercise of leadership elusive.

In the past, EPA was buffeted by
policy fashion as well as by legitimate
currents of change. Until the late
1960s, for example, environmental
control was seen as a problem of
public health protection, and was thus
housed in the Department of Health,
Education, and Welfare (HEW).
Gradually, however, the emphasis
began to shift from defining health
problems as guidelines for environ-
mental control to achieving techno-
logical solutions. The health problem
obviously remained, but Congress
decided that HEW was no place for
the development of technology or the
understanding of complex ecological
systems, and EPA was created.

It can be fairly stated that EPA
never could boast of a consistent
research policy. Hopes ran high during
its first two years when systems
analysts descended upon headquarters.
But systems mythology could only but
clash with traditions rising out of wet
chemistry and sanitary engineering.
Goals seldom squared with realities,
especially in environmental regulation
where research strategies were usually
dictated by crises emerging each week.
To be an EPA researcher was to be
unhappy. Besides being bureaucratically
overarching but arthritic, the agency

was acutely politicised by the Nixon
Administration.

Five year plan

Out of the wreckage—but in many
cases reflective of it—rises a five-year
research and development (R&D) plan
that Congress's Office of Technology
Assessment (OTA) has just finished
analysing for the committee on science
and technology. OTA has little good to
say of it; indeed, during the assessment
process, EPA scrapped the word "plan"
and substituted "outlook". It says in
essence that EPA's plan is not a plan
and as such is no guideline for helping
direct long term policies for the
country.

"Foremost among the shortcomings
in the R&D plan," OTA's report says,
"is EPA's failure to indicate a com-
mitment to long range research and,
as a corollary, an excessive focus on
short term R&D issues related directly
to the enforcement and/or achievement
of EPA's current regulations. Accord-
ingly," it goes on,

. . the Plan emphasises the development
and demonstration of control technologies.
In many cases, however, the larger prob-
lems involve social, economic and institu-
tional patterns which not only impede
technical solutions but which require
nontechnical approaches. To develop
effective overall environmental manage-
ment strategies will require more system-
atic and sustained socioeconomic research
efforts than those specified in the Plan.
An added R&D emphasis on long range
environmental concerns and a more res-
ponsive role to its lines of responsibility as
coordinator of Federal environmental
R&D would do much to enhance EPA's
effectiveness and credibility.

The US is obviously already envi-
ronmentally conscious. Whether it is
environmentally cleaner is another
question. The recent outbreak of the
so-called "legionaires disease" in Phila-
delphia appears to be caused by a toxic
metal whose origins and precise iden-
tity are still under investigation.
Evidence points to nickel carbonyl
from microcapsulised paper that re-
quires no carbon paper for the typing
of copies. Whatever the cause, the
point is that toxic chemicals are every-
where in the environment, and EPA
must always play a "catch-up" role.

But anticipation is the name of the
environmental game in its ideal, and
EPA's record as an anticipatory re-
search agency is a sorry one. Yet, anti-
cipatory research is a sorry subject
given the complexities of industrialisa-
tion and ecosystems. The obvious alter-

native is to require industry to stop
producing anything toxic to begin
with. EPA would administer the pend-
ing toxic substances control Act which
would do just that, but Congress seems
hesitant to pass a law so distasteful to
industry. It has been "pending" for
almost a decade. If passed, however,
EPA would become in theory much
like the Food and Drug Administra-
tion with its main regulatory goal being
prevention rather than reaction. Won-
dering what to react to has always
produced bureaucratic psychosis.

EPA's problems over the last few
years have been money, manpower and
morale. The EPA report doesn't
appraise the morale problem because
the charge was only to assess the Plan
itself. But the panels which gathered
to make the critique were composed
of individuals familiar with the agency's
internal problems and the moribund
psychology of the agency. That issue
wasn't discussed, despite its centrality.
The research arm of the agency is
plainly dejected. Individual scientists
know what needs to be done to begin
anticipating the environmental future,
but they know too that doing it would
require ten times the present research
budget of $250 million.

Questionable help

Thinking about environmental futures
is often a pathway to dejection, especi-
ally considering the fact that indus-
trialisation of the less developed
nations entails no pollution control to
speak of. And oceanographers have
long since despaired to any effective
pollution control policy for the oceans.

How much of a help OTA's critique
of the plan will be is questionable. It
says it isn't a plan. It says the main
issues are socioeconomic and EPA
hardly knows how to ask the right
questions in such a fuzzy area of para-
science. It says EPA knows next to
nothing about the long term effects of
pollution. It says EPA has a weak
health research capability. It is a
litany of deficiencies. The sorry fact is
that the same criticisms were made of
environmental research 15 years ago.

The findings have long since been
seen and mulled over by the House
science and technology committee. But
the practical and philosophical defi-
ciencies pointed out in the OTA report
transcend solution without profound
changes in consciousness among those
who make budgets and plan strategies.
And, of course, the entire milieu
within EPA would change once Con-
gress passes the toxic substances bill.
But that would mean further growth
in the regulatory bureaucracy and, of
course, larger costs of doing business.
The present Administration opposes
both.

BRITAIN_____

Genetic manipulation: guidelines out

Eleanor Lawrence studies the report on genetic manipulation experiments and the consultative document on regulations to control them.

GENETIC manipulation experiments involving artificially prepared recombinant DNA elements are to go ahead in the United Kingdom under certain specified conditions. Those intending to do such experiments must notify the Health and Safety Commission (HSC), an arm of the Department of Employment, and will also notify an independent Genetic Manipulation Advisory Group (GMAG) which will advise them of the conditions of containment required. The HSC is seeking powers to enforce the conditions recommended by the GMAG, and has put forward a set of draft regulations.

The voluntary code of practice and the proposed establishment of a national Genetic Manipulation Advisory Group are the main recommendations of the long-awaited report of the Williams Working Party on the Practice of Genetic Manipulation, published last week with government approval*. The aim of the technical guidelines and the machinery to put them into practice is to protect workers and the general public from the possible hazards presented by bacteria into which foreign genes have been transplanted by novel techniques developed several years ago in the United States.

These techniques enable DNA from another source (be it human, animal, plant, virus or an unrelated bacterium) to be spliced on to DNA from a phage or plasmid vector and introduced into a bacterium. The fear is that bacteria modified in this way (especially the common gut bacterium *E. coli*, a favourite of the genetic engineers) might present unpredictable dangers because of the new genes they possess, especially if the inserted DNA is not properly characterised or is known to contain potentially dangerous genes. The dangers could apply not only to the human and animal populations: harmless soil or plant bacteria into which genes from plant disease agents have been introduced could possibly pose a threat to crops.

But the advantages, both scientific and practical, which may eventually accrue from these new techniques are so great that there has been enormous pressure for the work to go on. Not

* *Report of the Working Party on the Practice of Genetic Manipulation* (Cmnd. 6600, HMSO, 50p).

only does it make it possible to clone particular genes and thus get to grips with many tricky problems in genetics, but specially engineered bacteria might eventually be induced to express the inserted genes and act as custom-built mini-factories making a valuable product quickly and cheaply.

Code of practice

The Williams working party was set up in response to recommendations contained in the Ashby Report which, in 1975, first considered the implications of the new genetic engineering techniques. Its brief was to establish a code of practice for conducting these experiments as safely as possible, and to define the role of the central advisory group which Ashby proposed. This, it was envisaged, would be responsible for ensuring that workers intending to perform genetic manipulation experiments were fully conversant with the safe microbiological techniques required.

Addressing the issue of matching particular experiments to the appropriate containment level, the working party has distinguished some 20 separate types of genetic manipulation experiment (see table) which they have then assigned to one of four levels of physical containment.

● **Category I**: Experiments must be carried out in conditions suitable for containing common human pathogens. (Because the introduction of alien DNA into a bacterium might have unforeseen consequences, the working party recommends that these precautions must be taken even when the source DNA, the vector and the host bacterium are all perfectly harmless in themselves).

● **Category II**: As I, but in addition the laboratory must be sited away from areas used by the general public and must have controlled air flow and an exhaust-protective cabinet for aerosol-producing operations.

● **Category III**: As II, but in addition access to the laboratory must be through an airlock only (which should contain washing facilities), all effluent from the laboratory must be decontaminated, and there should be an autoclave inside the laboratory.

● **Category IV**: Conditions should be equivalent to those already recommended in the Report of the Working Party on the Laboratory Use of Dangerous Pathogens for the most dangerous human and animal pathogens. (There are only a few such laboratories

in existence at present, for example those at the Center for Disease Control at Atlanta, Georgia, and at the Microbiological Research Establishment at Porton Down in the UK).

Genetic manipulation experiments can also be made safer using host bacteria and vectors which have been disabled so that they cannot grow outside a particular laboratory environment. Hosts can be crippled by introducing a requirement for some particular growth factor not found in the human or animal body, and disabled vectors which can only infect a special laboratory strain of host can be made.

The working party acknowledges the value of disabled organisms by assigning a lower containment level to experiments in which they are used, and recommends that research to develop new and better disabled strains be encouraged and the strains be made freely available.

Recommendations for implementation

The working party's recommendations are also concerned with the machinery needed to ensure that the code of practice is in fact followed. It recommends supervision at two levels, nationally

---

What is suggested ?

The Williams report recommends that:
1. experiments in genetic manipulation, conducted in appropriate conditions of physical and biological containment, should be encouraged.
2. further work should be done on the development and characterisation of disabled organisms and that any which are developed should be made freely available to all workers in the field.
3. no genetic manipulation experiment should be undertaken in containment conditions less stringent than those used for work with common pathogens.
4. the code of practice (in Appendix II) should be adopted as a basis for the conduct of these experiments.
5. every laboratory conducting these experiments should have a safety committee and a Biological Safety Officer.
6. appropriate training should be made available and be required for all research workers, technicians and biological safety officers in genetic manipulation laboratories.
7. a Genetic Manipulation Advisory Group (GMAG) should be established to advise on appropriate precautions for the conduct of these experiments.
8. the GMAG should be separate from the Dangerous Pathogens Advisory Group (DPAG) although there should be liaison between the two groups.
9. a system of voluntary control should be established as quickly as possible.
10. regulations should be made under the Health and Safety at Work Act to require laboratories to submit experimental protocols to the GMAG.

through the GMAG and, on the laboratory floor, in the person of a Biological Safety Officer, to be appointed in every laboratory in which genetic manipulation experiments are being carried out.

The Williams working party sees the central advisory group as crucial to the success of any control measures. One of its main functions will be to advise on the category into which a particular experiment should fall and on whether the laboratory is competent to carry it out. To do this the GMAG will need to maintain records of the facilities available in different laboratories; it should in time establish a register of approved laboratories. It should also review experimental protocols regularly and modify the code of practice in the light of new developments in biological and physical containment, and advise on training. The GMAG will be set up in the near future with a secretariat within the MRC, who will be responsible to the Secretary of State for Education and Science.

The biological safety officer will be the key person in the enforcement of correct procedures at the individual laboratory level. It will be his job to familiarise himself with the required techniques, and check that experiments are being carried out correctly; he will be responsible for training staff, investigating accidents and maintaining the security of the laboratory.

Recognising the "restraint already shown by the scientific community" since the voluntary moratorium on this work called for by American scientists two years ago, the working party now recommends that certain experiments which they consider do not present a serious hazard (Categories I and II, see table) should go ahead immediately, subject to notification to the GMAG. Experiments which fall into categories III and IV should not proceed until proposals have been approved by the GMAG.

In effect, the working party's technical guidelines are very similar to those published in July by the US National Institutes of Health, though there are important differences between the American and British approach. The US code of practice applies only to work carried out with NIH grants; the UK recommendations will apply to university government and industrial laboratories. The working party has also deliberately avoided the precise assignment of experiments with named organisms to particular categories.

Statutory control

The Working Party recommends that in the first instance the controls should be voluntarily imposed. But the draft regulations proposed last week by the Health and Safety Commission would provide some measure of statutory control without special legislation having to be passed.

The Health and Safety Commission is a government agency under the aegis of the Department of Employment set up to administer the Health and Safety at Work Act. This Act provides very wide powers to bring in regulations covering any work which might pose a hazard to the health and safety of work people and/or the general public.

The draft regulations, which are now being circulated as a consultative document to interested parties for comment, provide for compulsory notification to the Health and Safety Executive of all experiments which are "intended to alter, or likely to alter, the genetic constitution of any microorganism . . ." As it stands this blanket definition would cover practically all bacterial genetics experiments, and the Executive is asking the scientific community to recommend which conventional types of experiment should be exempted.

In addition the Executive wants to be able to enforce the precautions recommended by the GMAG through the Executive's Inspectors. They can already enforce general measures taken to avoid danger to health, but the Commission is inviting comments from any interested party on the need to include more specific provision for ensuring that the GMAG's advice is taken.

The ultimate sanction for researchers remains the witholding of a grant, however, and the working party recommends that, legal enforcement or no, government departments, research councils and other grant-giving bodies make grants conditional upon investigators following the advice of the GMAG. The working party also hopes that scientific papers will include a statement of both the physical and biological containment procedures used. □

Suggested categorisations for some typical experiments			
Source of nucleic acid	Specification of nucleic acid sequence	Vector/Host System	Category
Mammals	Random	Phage or plasmid/bacteria, not disabled	IV
	Random	Phage or plasmid/bacteria, disabled	III
	Purified*	Phage or plasmid/bacteria, not disabled	III
	Purified*	Phage or plasmid/bacteria, disabled	II
Amphibians and reptiles	Random	Phage or plasmid/bacteria, not disabled	III
	Random	Phage or plasmid/bacteria, disabled	II
	Purified*	Phage or plasmid/bacteria, not disabled	II
	Purified*	Phage or plasmid/bacteria, disabled	I
Plants and invertebrates and lower eukaryotes	Random	Phage or plasmid/bacteria, not disabled	II
	Random	Phage or plasmid/bacteria, disabled	I
	Purified*	Phage or plasmid/bacteria, not disabled	I
Mammals Amphibians and reptiles Birds	Random	Virus capable of infecting man or growing in tissue culture cells	IV
	Purified*	Virus capable of infecting man or growing in tissue culture cells	III
Viruses pathogenic to vertebrates	Random	Phage or plasmid/bacteria, disabled	IV
	Purified*	Phage or plasmid/bacteria, disabled	III
Animal viruses, non-pathogenic to man	Random	Phage or plasmid/bacteria, disabled	II
Bacteria specifying toxins virulent to man	Random	Phage or plasmid/bacteria, disabled	IV
Plant pathogenic bacteria	Random	Phage or plasmid/bacteria, not disabled	II
Plant viruses	Random	Phage or plasmid/bacteria, not disabled	II
Bacteria or fungi non-pathogenic to man, animals or plants	Random	Phage or plasmid/bacteria, not disabled	I

* The term "purified" means fractions with little chance of including any unrecognised extraneous sequences. It is of course possible to have sequences selected because of their pathogenicity and these would raise the level of containment required.

FRANCE

Musical chairs in science policy

As talk of changes at the highest levels of French government grew last month, the country's directors of research were already a few steps ahead. A Correspondent reports

THE directors of French scientific and technical research have recently been involuntary participants in a game of musical chairs organised by the government. First, the president of the Centre National d'Etudes Spatiales (CNES), Professor Maurice Lévy, was dismissed by the Minister of Industry and Research, M Michel d'Ornano, for making concessions to striking staff that his assistant had refused to grant in his absence. He has yet to find another post. On the same day, Professor Curien, head of the Department of Scientific and Technical Research (DGRST), replaced Professor Lévy. The move, from a department which coordinates and implements all research policies (except military projects) to a directly operational post, has drawn much comment.

A few days later, Professor Curien, who was director of the Centre National de la Recherche Scientifique (CNRS) until 1973, was replaced at the head of the DGRST by Professor Grégory, who had previously taken his place at the CNRS. Then, to complete these acrobatics, which incidentally only involved physicists, the director of physics at the CNRS, Professor Chabbal, became director-general of the CNRS at the beginning of August.

The government—and in particular M d'Ornano—has shown in this series of decisions an unexpected authority and haste at a time when the credibility of those in power is constantly weakening. The circumstances of the CNES affair are fairly clear. The shrewd and effective Professor Lévy was forced to leave because of the Minister's change of mood—a change which neither his colleagues nor his advisers, who saw the opportunity to bring about other changes, sought to influence. A review of the allocation of the space budget between the programmes of the European Space Agency and the French programme had been due since European agreement on the level of the Agency's activities. The new allocation brought about some changes in the CNES budget which were to make some of its staff redundant, particularly at Toulouse.

With France wanting to guarantee Europe's autonomy regarding applications satellites, especially telecommuni-cations (the last breath of the great Gaullist doctrine of independence), the CNES gave priority to completing the launcher Ariane. (The Ariane project's director, Yves Sillard, became director of the CNES and assistant to the President a few weeks ago.) Under the threat of redundancies, CNES workers went on strike. The CNES directors were unwilling to give in to the strikers' demands, and maintained their position for several days, only to be overruled in the end by their president, who took the side of the employees. The government, however, intervened.

The causes of the stir this provoked in the research policy establishment are more complex. Two main characteristics differentiate research in France from research in other countries. The arrangement in the universities, where there is an even split between research and teaching, is unsatisfactory; information about what is going on does not permit either good financial management or national coordination. In accordance with the recommendations of the VIIth Plan, the Secretary of State for the Universities, who is responsible for university research and the CNRS, has created a "Research Mission" directed by Professor Denisse, who was Professor Lévy's predecessor as president of the CNES. The purpose of this mission is to re-organise university research.

The other characteristic of French research is the endemic weakness of industrial and technical research. French industry does not spend enough money on research, as M d'Ornano recently pointed out in parliament. Moreover, public funds normally allocated to industrial research are often put to other uses financing industry. The DGRST, which is for the most part made up of specialists in basic research and is directed by a laboratory physicist, often has great difficulty understanding industrial problems. This results in disagreements with other administrative departments concerned with industry, technology and financial management.

Thus the DGRST often ends up giving its funds (FF640 million in 1976) to the same laboratories. In an attempt to resolve this problem M d'Ornano asked the fiery director of the Centre National d'Etudes des Telecommunications (CNET) for a report on industrial research last April. One of the conclusions of the report was that a sub-department of industrial research and technology should be set up, linked to the Department of Research.

Michel d'Ornano

This proposal was strongly attacked by the DGRST: by its staff on the one hand who, like any other body, do not like the idea of being restructured by a logic they do not understand; and on the other hand by the director, Professor Curien, who distrusts dyarchies. The director was therefore moved to the CNRS. He was replaced by Bernard Grégory, who is also a former director of CERN. The Minister meanwhile stated that a technological representative will be nominated.

The proposal was also strongly attacked initially by another department, the Department of Mines. Although not implied by its title, this department is concerned with industrial research. It is the fiefdom of "mining engineers", a technocratic elite formed by the greatest of the "Grandes Ecoles", the Ecole Polytechnique. The mining engineers have an undying sense of unity: some hold high positions in the Administration, others are responsible for a large number of French industrial enterprises.

With these connections and the technical control of enterprises and industrial products that have by law fallen to it, the Department of Mines has developed a very different concept of industrial research and development from classical French practice since 1958. It is interested in the traditional industries; it tries to encourage collective research, common to all firms in the same sector; it checks that each project follows the objectives of the government (in conservation of energy, improvement and quality of products, working conditions and so on) through a complex series of committees. In short, it can take action effectively on scientific and technical information, industrial ownership, standardisation—and on funds.

If the future technological representative does not share its philosophy, there will be serious conflicts. And the stakes are high, especially for those enterprises which draw extensively on the research budget. ☐

IN BRIEF

EEC uranium scheme

Last week's announcement by the EEC Energy Directorate of a £400,000 scheme to support uranium prospecting within the EEC member countries came just two months after the report from Euratom forecasting a shortfall in uranium supplies for Europe from the end of the decade. Euratom expressed concern that there was no coverage either by long term contracts or from known reserves of Community producers, and urged an acceleration in exploration and development. The

Energy Directorate says it hopes the new project will discover new uranium sources to secure the EEC's long term supply.

No postgraduate change

The UK Department of Education and Science has declared in a White Paper (Cmnd 6611, HMSO, 28p) that it does not intend to restructure the arrangements for supporting postgraduate education in Britain. It was responding, after a delay of 2½ years, to strident criticisms of the system

voiced by the House of Commons Expenditure Committee. The committee's main contention was that postgraduate education should be shaped chiefly by the needs of the country rather than by the demands of potential students. The DES, while agreeing in broad principle, says that bodies like the research councils are already sufficiently responsive to these needs. The DES also rejects the idea that postgraduate grants should be replaced by any kind of loan, because the short term savings in government expenditure would not be sufficient.

IN theory, the more data a scientist is able to collect, the more accurate his work should become. On the other hand, a great deal of information is expensively collected and then never properly used. Sometimes this is a symptom of oversupported research; a scientist who has to do his own field or laboratory work is generally careful how he uses his time, but if he can deploy a squad of assistants he may ask them to make many more observations just in case these may, eventually, prove valuable. And very occasionally they do. But most of the results of even the best planned research remain untouched in dusty archives or even end up in the waste paper basket, although some work is written up and submitted for publication before sufficient information has been collected. It is not easy to decide when is the right time to stop.

An even more difficult task for the research worker is to decide just what data should be collected. If, to obtain a grant or a fellowship, he has to draw up a detailed programme in advance, he is unlikely to make the same decisions as he would have made after he had become immersed in his problem, particularly if he were personally involved in the details of the work and did not delegate to assistants. It is therefore essential that all research projects should have some provision for review and redeployment at frequent intervals.

But where a team of investigators is involved, such changes of direction may be difficult, as all members may not agree on just what changes are desirable. Even the lone worker may be inhibited from modifying his programme when he realises that this is necessary, in case he upsets the members of some committee to which he reports. Committee members react in this way, and castigate those who suggest that their original submission was faulty, perhaps because they themselves feel guilty for not spotting

the faults earlier.

We may collect too many or too few data, and we may also amass figures which do not provide the information that was intended. This is unfortunately too common an occurrence, and one which may long

Testing rainwater
KENNETH MELLANBY

---

go unrecognised, as has recently been demonstrated in work on air pollution. Many people are studying problems which involve the contributions to plants and the soil made by the various chemicals contained in rain. Perhaps the best known is that of "acid rain" in Scandinavia, allegedly caused by pollutants, particularly SO_2, released into the air by British and European industry and carried north by the prevailing winds. Other work concerns the growth of crops and trees in polluted and clean localities. Unfortunately few of those involved are making systematic analyses showing exactly what substances are being brought down in the rain.

To many, including some of the investigators, this will appear to be a surprising statement, for numerous

people in many countries are analysing rainwater samples by the thousand, with increasingly accurate methods and more and more sophisticated equipment. There is little reason to doubt the accuracy of their measurements. Unfortunately they are not, for the most part, studying rain, but the liquid which they collect in their rain-gauges. This is something quite different, for it contains not only the chemicals which took part in the formation of raindrops, and those which were collected by the drops as they fell through the air, but also those which had been deposited, since the last shower, on the collecting funnel of the rain-gauge. The dry deposition on the gauge is generally greater, sometimes many times greater, than the quantity of the same chemical in the rain. If this is not realised, and measured, errors of a magnitude seldom experienced in research may arise.

Yet there is no excuse for this possible error. There is a little published information, available for some years, showing how much rainwater may differ from rain-gauge water. We cannot yet say exactly what the dry deposition of materials on any field, crop or forest will be, but there is much elegant work attempting these evaluations, and it is already clear that it greatly exceeds that in the rain, or even that in the already-enriched rain-gauge water.

Those who have spent time and effort analysing rain-gauge water, thinking they were analysing rain, need not despair. Their data are far from useless—they only fail to give the information expected. But this is a common phenomenon in science, and is one of the reasons to be suspicious of too highly orgaised investigations, particularly those commissioned by customers who think they can guarantee that the new information they seek can always be provided if only the cash is made available.

Stratified waters hold the key to the past

from M. Whitfield

THE history of the oceans and the atmosphere is, so far as we can tell, a story of the progressive oxidation of the primordial anoxic environment (F. T. Mackenzie, *Chemical Oceanography*, Riley, J. P. and Skirrow, G., eds, 1, ch. 5; 1975). Reducing conditions on the primitive Earth were an essential prerequisite for the formation of organic compounds from inorganic ingredients by a biological process. Oxygen was initially generated by photochemical processes in the atmosphere but large scale oxidation probably did not occur until photosynthetic blue-green algae began releasing free oxygen into the oceans some 3 billion years ago.

Over large areas of the present-day ocean, a permanent density discontinuity (pycnocline) arises as a consequence of the latitudinal variation in the intensity of incident radiation from the Sun which warms the tropical and subtropical surface waters and drives the cold polar waters into the ocean depths. This stratification stabilises the oceanic water column and restricts mixing between water in the sunlit euphotic zone and water from the abyssal depths. It is likely that the pycnocline has been an important feature of the structure of the oceans throughout most of their history (P. K. Weyl, *Science*, **161**, 158; 1968). After the development of photosynthetic cells the pycnocline would also mark the boundary between oxygenated and anoxic water and the resulting stratification would accelerate the build-up of oxygen in the upper layer and enhance the evasion of oxygen into the atmosphere. According to the Berkner–Marshall hypothesis (L. V. Berkner and L. C. Marshall, *J. atmos Sci.*, **22**, 225; 1965) the subsequent build-up of atmospheric oxygen played a crucial part in the development of higher life forms since it promoted the switch-over from a fermentative to a respiratory metabolism which was essential for the development of the nucleated eukaryotic cells that are the essential building blocks of all multi-

cellular organisms. The concomitant strengthening of the ozone layer provided a progressively more effective shield against ultraviolet radiation which made possible the colonisation of the energy-rich surface waters of the ocean and eventually the colonisation of the land. The interplay between processes that generate oxygen and processes that consume oxygen in stratified waters is therefore of central importance to any attempts to understand interactions between evolving life forms and their environment.

Pictures of a stratified Precambrian ocean previously developed to explain evolutionary processes (D. C. Rhoads, and J. W. Morse, *Lethaia*, **4**, 413; 1971) or geological phenomena (H. D. Holland, *Econ. Geol.*, **68**, 1169; 1973) have postulated a rather stable, layered system undergoing gradual oxidation over the past 2 or 3 billion years. E. T. Degens and P. Stoffers in this issue of *Nature* (page 22) relating the evolution of the early oceans to the recent history of present-day stratified waters suggest a more variable and dynamic history.

In strongly stratified systems the upper, oxygenated layer is relatively alkaline (*p*H 8 to 9), the levels of the major nutrients (nitrate, phosphate, silicate) are kept low by the incessant biological activity and carbonate minerals can be precipitated by inorganic or biological processes. The lower layer, by contrast, is more acid (*p*H 6.5 to 7) and contains hydrogen sulphide and abundant nutrients (ammonia, phosphate, silicate) and free carbon dioxide resulting from the decay of organic matter drifting down from the surface. This layer is also enriched in metals such as iron, manganese and nickel that are soluble in the reduced form. In the lower layer the variety of life forms is restricted to members of the sulphur biome (T. M. Fenchel and R. J. Riedl, *Mar. Biol.*, **7**, 255; 1970) probably the oldest ecosystem on earth.

The stability of the stratified condition depends on the dynamic balance

maintained between the water recirculation (recharging oxygen) and the degradation of organic matter (consuming oxygen). A rapid change in the depth of the pycnocline will cause a hiatus in the water chemistry which will leave its record in the sediments. A rapid downward movement will cause dramatic precipitations of iron, manganese and carbonate minerals and the corresponding injection of nutrients will stimulate plant growth in the oxidised layer. This growth will in turn increase the oxygen demand below the pycnocline and speed up the re-establishment of anoxic conditions. If the pycnocline now moves upwards some of the precipitated minerals (particularly the carbonates) will be re-dissolved and the incursion of hydrogen sulphide will ensure a massive extinction of bottom-living (benthic) organisms. The banded sediments of the Black Sea and the East African rift lakes observed by Degens and Stoffers, with the precipitates forming discrete layers rather than being dispersed amongst the regular detritus, suggests that the depth of the oxygenated layer has oscillated widely in response to climatic variations and to tectonic and erosional forces throughout the Holocene and Pleistocene. The pattern of variation is strikingly similar in the various locations and, furthermore bears a much closer resemblance to Cambrian and Precambrian sedimentary deposits than do modern oceanic sediments. These similarities suggest that the trend towards an oxygenated ocean might have suffered many reversals and that the details of these reversals are held in the sedimentary record, awaiting interpretation.

The oscillating pycnocline would certainly provide a particularly elegant explanation for the widespread banded-iron formations (rythmic sequences of iron-rich deposits interleaved with iron-poor cherts) that first appear in the sedimentary record 3 billion years ago and disappear fairly abruptly 1.2 billion years later. More dramatic upheavals of the system could also be engineered

to explain the periodic ecosystem collapses that have occurred at intervals of roughly 150 million years since Cambrian times (H. Tappan, *Palaeogeor.*, *Palaeoclimatol. Palaeoecol.*, **4**, 187; 1968). The analysis by Degens and Stoffers, particularly of deep sediment cores taken from the Black Sea by the Glomar Challenger, will enable such hypotheses to be tested quantitatively and should allow more definite statements to be made about the stresses that accompanied shifts of emphasis in the evolutionary process in the oceans.

These reminders of instability may also contain a word of warning. Natural control mechanisms are fairly delicately balanced and they often work by a process of overshoot and damping rather than by rigorous control within fine limits. As the Baltic countries are finding to their cost, increased oxygen demand resulting from industrial effluent can quickly generate oxygen-deficient bottom water in an enclosed sea. Similar problems have occurred in the Great Lakes of North America and have recently been reported in Lake Baikal. Furthermore, artificial upwellings proposed both as a source of power and as a means for stimulating planktonic growth in the surface waters of the oceans may also generate oxygen-deficient bottom water unless they are located with care.

Maintenance and evolution of repeated genes in eukaryotes

from D. Glover

THE genes for 5S RNA and ribosomal RNA are highly repetitive and occur as tandemly repeated clusters within eukaryotic genomes. These genes are separated by so-called spacer sequences which are not transcribed. Two main theories have been proposed to explain the mechanism by which tandemly arranged sequences are kept relatively homogeneous and how the genes and their spacers have evolved together. At the one extreme, are the sudden correction mechanisms such as Callan's "Master-Slave" hypothesis in which many genes are simultaneously corrected against a master template. At the other extreme, gradual correction mechanisms have been proposed which involve unequal crossing-over between homologous chromatids in such a way that variants could be spread or eliminated from tandem genes. The spacers of the genes for 5S DNA and rDNA in *Xenopus laevis* have now been subjected to elegant molecular analysis and this has cast some light on these problems.

The 5S DNA of *X. laevis* has an AT-rich spacer which consists largely of repeated units of simple sequence DNA (Brownlee *et al.*, *J. molec. Biol.*, **89**, 703; 1974). Carroll and Brown (*Cell*, **7**, 467; 1976) have recently described evidence which indicates that there is considerable heterogeneity with respect to length in this spacer sequence. Cleavage with the restriction endonuclease *Hind*III occurs at one site in each 5S gene and generates a series of closely spaced bands each of approximately 700 base pairs. These bands differ in length by regular increments of 14 base pairs which is the length of the simple sequence unit described by Brownlee *et al.* Carroll and

Brown went on to make partial *Hind*II digests of gradient purified 5S DNA, and have cloned these fragments. Each cloned DNA contains up to five of the 5S genes within a DNA plasmid of *E. coli* (*Cell*, **7**, 477; 1976). Denaturation mapping of these cloned 5S genes indicates that adjacent genes can be heterogeneous in length. It is unlikely that such arrangements could be found if sudden correction mechanisms were operating during evolution and Carroll and Brown come down strongly in favour of a mechanism of unequal crossing over between the AT-rich spacers in which the sub-repeats are essentially homologous.

Wellauer *et al* (*J. molec. Biol.*, **105**, 461; 1976) have now made a similar analysis of the ribosomal genes from *Xenopus laevis*. There are two classes of *Eco*RI fragments which can be excised from the gene unit. One of these is homogeneous for length whereas the other class of fragment is heterogeneous for length and contains non-transcribed spacer sequences. Four representatives of this latter class have been cloned within *E. coli* and then characterised by homoduplex and heteroduplex mapping. This has revealed two regions within the non-transcribed spacer which vary in length and seem also to consist of repetitious simple sequences, the subunit of which is shorter than 50 base pairs in length. In *X. laevis* the ribosomal genes of oocytes undergo substantial amplification, a process which is thought to occur by a rolling circle mechanism of DNA replication (Hourcade *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **70**, 2926; 1973; Rochaix *et al.*, *J. molec Biol.*, **87**, 473; 1976. If this is so, then one would predict that adjacent rDNA genes from oocytes

would be more homogeneous for length than adjacent rDNA genes from somatic tissue. Wellauer *et al.* (*J. molec. Biol.*, **105**, 487; 1976) have examined heteroduplex structures formed between either long single-strand chromosomal or amplified rDNA and a cloned segment of rDNA and have found that this is indeed the case. In a third paper, the same group has found that not only is there heterogeneity in spacer lengths, but also that the pattern of spacer lengths is significantly different from one animal to another so that it can be followed as a genetic marker (Reeder *et al.*, *J. molec. Biol.*, **105**, 507; 1976). The patterns of spacer heterogeneity are stably inherited from one generation to the next and only two animals out of 50 showed changes in their spacer patterns. The mechanism by which these two changes arose remains an open question.

The tandemly repeated gene clusters of *Drosophila melanogaster* are also producing their share of surprises. The nucleolus organisers of *D. melanogaster* are found on both the X and the Y chromosome. In wild-type males there is apparently no meiotic recombination and so the two nucleolus organisers are genetically isolated from one another on non-homologous chromosomes. The rRNA transcribed from either the X or the Y seems to be identical however. A single ribosomal gene unit from this organism has been described which from the evidence of DNA reassociation kinetics also contains about 3,000 base pairs of internally repetitious simple sequence. There are two major size classes of rDNA, one in which the repeating gene unit is 17 Kbases in length and the other in which the repeating gene unit is 11–12 Kb in length (Glover *et al.*, *Cell*, **5**, 149; 1975). Tartof and Dawid (on page 27 of this issue of *Nature*) have examined the distribution of these two units on the X and Y nucleolus organisers and find that whereas the 11–12 Kb unit is present on both the X and Y chromosomes, the 17 Kb unit is found only on the X. This suggests that indeed recombination is not occurring between the X and Y rDNAs, unless there is some specific mechanism for eliminating the 17 Kb units from the Y chromosome.

The mechanism whereby the identity of the rDNA sequences on the X and Y chromosomes is maintained is obscure, and indeed it will be interesting to have a comparison of spacer sequences on the 12 Kb and 17 Kb units which have been cloned in *E. coli*. The mechanism of the maintainance and co-evolution of these tandomly repeating genes may turn out to be even more complicated than the experiments with *Xenopus* 5S DNA and rDNA suggest.

T cell recognition at Cold Spring Harbor

from Martin Raff

The XLI Cold Spring Harbor Symposium on Quantitative Biology, entitled Origins of Lymphocyte Diversity, was held on June 1–8, 1976.

SINCE the symposium covered most of present-day immunology this is an attempt to cover just one area—how T cells recognise antigen. In my view, it was recent progress in this knotty area of immunology that provided much of the excitement at the meeting.

While it is clear that membrane-bound immunoglobulin (Ig) molecules serve as receptors for antigen on B lymphocytes, the nature of antigen-specific receptors on T cells has been elusive and, for the most part, unproductively controversial. Now, at last, half of the problem seems to be resolved, with the demonstration that at least one receptor on T cells is a new class of Ig heavy(H) chain, which may come to be known as "tau" (τ). The strongest evidence for this was provided by H. Binz and H. Wigzell (Uppsala University), who, following the lead of Ramseir and Lindenmann[1], have approached the problem using antibodies directed against antigenic determinants associated with the antigen-binding sites of Ig molecules—so-called idiotypic determinants.

They had previously shown that anti-idiotypic antibodies (raised in (Lewis × BN) F_1 rats against Lewis anti-BN alloantibodies, or against Lewis T lymphocytes) react with both T and B cells of Lewis rats which bear receptors specific for the major histocompatibility complex (MHC) antigens of BN rats[2]. Thus, T lymphocytes seem to express some of the same idiotypes as conventional antibodies—a notion supported by similar findings obtained independently by others, in rats[3] and mice[4]. Binz and Wigzell have now shown that whereas the idiotype-bearing (and BN-antigen-specific) receptors on Lewis B cells are 8S IgM molecules, those produced by T cells are polypeptide chains of molecular weight approximately 75,000 daltons, which may exist as dimers and which do not react with conventional anti-Ig antibodies or with antibodies directed against Lewis MHC antigens (which presumably include activity against both Ag-B and I-region-associated (Ia) antigens). Moreover, they reported that these in-

herited idiotypes are genetically linked to a Lewis Ig H chain allotype, indicating that the idiotype-bearing receptors on T cells are coded for in the H-chain variable region (VH) gene pool. Since the isolated T cell receptors seem not to be tightly associated with other polypeptides of different molecular weight, the simplest view is that single or dimeric Ig H chains, having a previously undescribed constant region, serve as receptors for antigen on T lymphocytes.

The findings reported by K. Eichmann (German Cancer Research Centre, Heidelberg) and K. Rajewsky (University of Cologne) and their colleagues were consistent with this view. They had previously used anti-idiotype antibodies raised in guinea pigs to show that both T helper cells and B cells in A strain mice use the same inherited VH genes for responding to Group A streptococcal carbohydrate[6]. They have now found that only those anti-idiotype antisera that recognise idiotypes genetically linked to H chain allotypes (and which are therefore related to the H chain alone) are able to stimulate (prime) both T and B cells *in vivo*, whereas those that react with idiotypes that require light (L) chains for their expression can only stimulate B cells In addition, using hapten-coupled nylon mesh to purify rabbit lymphocyte receptors, they reported the presence of VH allotype determinants on putative T cell receptors which bind antigen but fail to react with antibodies against constant region antigenic determinants of Ig L or H chains

The other side of the T cell recognition puzzle concerns the target antigens that T cells see. There is increasing evidence that T cells only respond maximally to conventional antigens when they see them in association with MHC antigens. Thus, in order for cytotoxic T cells to respond optimally to viral[6], haptenic[7] or minor histocompatibility[8,9] antigens on mouse target cell surfaces, they must see them in association with H-2D or H-2K gene products; T cells that proliferate in response to antigen-coated "macrophages" *in vitro*, recognise antigen in association with the Ia antigens of the "macrophage" (ref. 10 and W. Paul, National Institutes of Health); helper T cells seem to see antigen in association with Ia antigens (C. Pierce, Harvard Medical School; M. Feldmann and

P. Erb, University College London; H. Von Boehmer (Basel Institute for Immunology) and J. Sprent (University College London)), and T cells responsible for delayed hypersensitivity see some antigens (foreign gamma globulin, for example) in association with Ia antigens, and others (such as dinitrofluorobenzene) in association with H-2D or H-2K gene products (J. Miller, Walter and Eliza Hall Institute, Melbourne).

In most of these situations, the associative recognition of MHC antigens can involve syngeneic or allogeneic MHC determinants; however, the MHC context (syngeneic or allogeneic) in which antigen is first seen by T cells in a primary response is "remembered" by the primed T cells and must be the same MHC context if these cells are to give a secondary response to the antigen. This has been shown for cytotoxic T cells (Zinkernagel and Doherty; Von Boehmer and Sprent), helper T cells (Von Boehmer and Sprent; Pierce; D. Katz, Harvard Medical School) and T cells mediating delayed hypersensitivity (Miller), and explains most experimental results which had previously been considered examples of "syngeneic preference", where it was thought that T cells and macrophages[10], or T cells and B cells[11] had to be syngeneic for I-region determinants in order to collaborate. The meshing of the findings in all of these T cell systems is both comforting and exciting. Together, the observations underline the central importance of the MHC in T cell recognition, which must be one of the most important advances in immunology in recent years.

What does this mean in molecular terms? If the same inherited VH genes are used by helper T cells and B cells in A strain mice to recognise Group A streptococcal carbohydrate[6], and the helper T cells (but not B cells) recognise this antigen in association with Ia determinants, then it seems highly probable that the T cells use a different gene product for recognising the Ia antigens Since, so far, allelic exclusion has only been shown for B cells it is conceivable that two different VH gene products are involved, one maternal and one paternal. It seems more likely, however, that T cells make two genetically independent receptor molecules, just as B cells make genetically unlinked L and H chains; unlike the B cell receptors, however, the two T cell receptors may not be physically associated on the cell surface. More evidence for two independently coded T cell receptors is provided by Heber-Katz and Wilson[13] who found that T cells positively selected for reactivity against MHC antigens are as effective as unselected T cells in helping B cells respond to sheep erythrocytes. The

pressing need now is to identify the putative "second" T cell receptor; less pressing is the need to establish whether the "antigenic" and MHC determinants have to be physically associated, either on the target cell or "macrophage" surface, or as a shed complex[13]. In any event, the notion that T cells look primarily at a single compound determinant, in the form of antigen-modified MHC glycoproteins ("altered-self")[14] seems improbable.

If there are two classes of antigen-specific receptors on T cells, the undefined "second" receptor presumably recognises mainly self and foreign MHC antigens. Yet, Binz and Wigzell report[15] that 3–5% of Lewis T cells label with their anti-idiotype antibodies, which are thought to react primarily with those VH gene products that recognise BN MHC determinants. Therefore, it seems that both the VH and the putative "second" T cell receptor gene pools may be heavily committed to recognising MHC antigens and that Jerne[16] may have been right—yet again.

With the demonstration that Ia antigens are important in associative recognition by T cells, the list of I-region functions continues to grow. Various Ia antigens have now been identified on the surfaces of B cells and "macrophages" (see ref. 17), suppressor (D. Murphy and L. Herzenberg, Stanford; M. Feldmann, University College London) and helper (Murphy and Herzenberg) T cells, on enhancing and suppressing factors probably produced by macrophages (Feldmann and Erb) and T cells (T. Tada, Chiba University, Japan; and ref. 18), and on acceptor sites for such factors on T (Tada; Feldmann and Erb) and probably B lymphocytes[18]. The simplest view is that most, if not all I-region loci are involved with T cell responses or T cell regulation of B cell function, and that the I-region Immune response (Ir) genes, which regulate T-cell dependent immune responses to a variety of specific antigens, exist at many, if not all, of these different loci, and do not primarily code for T cell receptors. That immunity to a single antigen can be controlled by more than one Ir gene has already been established (B. Benacerraf *et al.*, Harvard Medical School; and refs 18–21) as has the fact that these genes can be expressed in macrophages (or in cells that copurify with macrophages)[18].

Until now, the biology of T lymphocytes has lagged well behind that of B cells—but the pendulum has reversed its swing. Unravelling the functions, biochemistry and genetics of the products of the MHC, now recognised to be central to T cell function, is providing most of the action in immunology these days and the Cold Spring

Harbor Symposium was a celebration for those involved.

Finding a niche

from Peter D. Moore

THERE are few terms in ecological jargon which are used more frequently than the 'ecological niche' and there are few which have been used so loosely. This is particularly true in plant ecology where there have been few attempts to construct working definitions. The use made of the term by Elton (*Animal Ecology*, Sidgwick and Jackson, London; 1927) was essentially applicable to animals and referred to the role of a species in a community as far as its feeding and competitive interactions are concerned. In autotrophic plants the variety of functional roles available is obviously severely limited, so the Eltonian concept of niche has not proved particularly valuable.

Hutchinson (*The Ecological Theater and the Evolutionary Play*, Yale University Press, New Haven; 1965) has provided a concept of 'niche' which is of much greater value to plant scientists. If one considers all the possible environmental factors which influence a species, and the organism's response to these factors, then these can be regarded as axes in multi-dimensional space. Each species thus occupies a definable volume of 'hyperspace', which represents the set of conditions under which the species can survive. This potential or 'fundamental' niche, may not be identical to its 'realised' niche, for competitive interactions between species whose fundamental niches overlap may result in their restriction within their potential volume. Wuenscher (in *Handbook of Vegetation*

Science No. 6, edit. by Strain, B. R. and Billings, W. D., 39, Springer Verlag, Berlin, 1974) has discussed the Hutchinsonian concept of niche as it applies to plants and has also stressed how the concept goes beyond that of simple habitat. Any point within niche hyperspace can be described by the coordinates of all the environmental variables (habitat factors) and the response of the organism to these factors. The response element carries the niche concept beyond that of habitat alone.

In a community it is to be expected that the component species will occupy adjacent hyperspace volumes, since their basic habitat requirements will be similar In this case, the introduction of a new species can only be successful if other species are permanently displaced from at least part of their former niches. Total displacement will, of course, result in extinctions. An example of this situation was described in some detail, by Zaret and Paine (*Science*, 182, 449; 1973) following the introduction of an exotic cichlid fish, *Cichla ocellaris*, into Gatun Lake in the Panama Canal Zone. This predatory species caused considerable simplification in community structure by supplanting several native species. Examples from the plant kingdom are not as well documented, but they certainly exist. The abundance of the sycamore (*Acer pseudoplatanus*), introduced into British woodlands probably in the early sixteenth century, has almost certainly been achieved only at the expense of native species, but it would be difficult to prove this.

There are situations in which an introduced species appears to have no deleterious influence upon the native components of a community. If such a situation does occur, it implies that the niche of the invading species has no volume of overlap with those of the natives. It has recently been claimed by Hudson (*Brit. Birds*, 69, 132; 1976) that the North American ruddy duck (*Oxyura jamaicensis*) which has become feral in Britain over the past 30 years, has occupied a 'vacant niche' in that its ecological requirements overlap little with such native diving ducks as the pochard (*Aythya ferina*) and tufted duck (*A. fuligula*). In Hutchinsonian terms, the niche can only be defined in terms of environment and species response, so strictly one should not speak of 'vacant niches', however the idea of an untapped environmental resource is often referred to in this way. The former vacancy in hyperspace can only be recognised in retrospect.

Danin (*Oecologia*, 22, 251; 1976) has recently conducted a survey of annual plant species under desert conditions in the Dead Sea Valley of Israel. He showed that diversity falls with increas

MAN'S first picture of the surface of Venus caused great interest and some surprise as it revealed that Venus, like Mercury, Moon and Mars, had a cratered surface. The picture was obtained using simultaneous Doppler and time delay processing of 12.6 cm wavelength radar echoes reflected from the surface (Rumsey *et al.*, *Icarus*, 23, 1; 1974). Looking at a 1,500 km diameter circular area at the centre of the planetary disk on June 20, 1972, they found it to be nearly flat but cratered. The biggest crater was 160 km in diameter, the floor appearing to be on the same level as the surrounding terrain but with the rim 500 m above the floor. By contrast a lunar crater of this size would be about seven times deeper.

Venus and Earth have fairly similar masses and both seem to have large raised regions on their surfaces. The "continents" on Venus do not appear to be isostatically compensated so that active internal convection may be taking place coupled with a degree of surface volcanism. Craters will be formed both by volcanic activity and by meteoritic activity; however, the information needed to determine which phenomenon is more likely is still lacking.

Michael Tauber and Donn Kirk (NASA–Ames Research Center) have now attempted to determine the sizes of the stone and iron meteoroids which can penetrate the atmosphere of Venus and cause hypervelocity impact craters on the planet's surface (*Icarus*, 28, 351; 1976). Obviously the surface pressure of 90 atmospheres and the atmospheric density of 64 kg m^{-3} present a major obstacle to the passage of meteoroids Ninety percent of the meteoroids will have atmospheric entry velocities ranging from 10 to 40 km s^{-1} and if all of the kinetic energy lost by atmospheric

drag was available to heat and vapourise the meteoroid no meteoroids less than 10^{11} kg in mass would survive passage through the atmosphere Actually only a small fraction of this energy goes to heat the body, the great majority's being lost as it heats the atmospheric gases The complex interactions between the body and the high temperature–high pressure shock layer surrounding it make the mass

Venusian craters
from David W. Hughes

loss calculations very difficult. Tauber and Kirk find that bodies over 10^4 kg only lose a few percent of their mass by vapourisation, mainly because entry takes place so quickly. The velocity of the body can decrease drastically though.

A hypervelocity impact crater is produced when the shock pressure at the impact point exceeds the compressive dynamic strength of the target material. Venera 8 measurements suggest that Venus has a granite-like surface material and the authors calculate that basalt and iron projectiles with velocities greater than 1.1 km s^{-1} and 0.7 km s^{-1} will produce hypervelocity impacts and craters. For basalt and iron particles they find that it is only those larger than 100 m and 40 m that have final velocities above these limits. One complication is the possible mechanical break-up of the body before impact. This is caused by a combination of thermal stress from frictional heating and also air pressure acting on the high speed body as it is retarded in the atmosphere. Frictional heating is confined to a thin shell and probably does not affect large meteoroids. The atmospheric forces on the other hand become very large and may exceed the compressive strength. It seems

that for large bodies this only happens for a second or so before impact so there is not enough time for the cracks to spread throughout the body or for fragments to separate significantly So on Venus this effect does not change the size of the crater produced. The authors calculate that a stone meteoroid 1 km across, entering the Venusian atmosphere at 40 km s^{-1} will produce a crater 33 km in diameter. This diameter is proportional to the sixth power of the particle's density and its kinetic energy raised to the power 0.28. They also find that the smallest hypervelocity impact crater on the surface of Venus is about 150 to 300 m across. This contrasts dramatically with the Moon which has no atmosphere to retard or fragment the meteoroids and is pockmarked with craters of all sizes greater than a fraction of a micrometre

Venera 8 measurements (*Icarus*, 20, 407; 1973) indicate very low surface winds on Venus so the crater structure may be preserved for long periods of time. The radar picture taken by Rumsey *et al* had a resolution of about 12 km, so it cannot be used to test Tauber and Kirk's theory. Radar mapping from a planetary orbiter, or radar using the Arecibo radio telescope could provide the resolution In fact photography from a probe descending through the Venusian atmosphere is possible as the daylight illumination level at the surface is thought to be about 2% of that on Earth. The discovery of primary impact craters smaller than the 150–300 m calculated above would indicate that the impacts occurred when the atmosphere of Venus was less dense than it is now. So crater size distribution thus provides a straightforward indication of atmospheric evolution

---

ing soil salinity until eventually, in highly saline conditions, only one species, *Mesembryanthemum nodiflorum*, survives. Danin describes this gradient as one in which a physiological stress reduces the number of niches until, under extreme stress, a one niche habitat results. This situation does not preclude competitive interplay, but demonstrates the superior growth potential of the surviving species under the stress conditions In the Hutchinsonian sense it can thus be termed a one niche habitat What one must not discount, however, is the possibility that there could be unrecognised opportunities even here for species which have either not yet invaded, or may not even yet have evolved in the area. Could one term such an availability of

opportunity, such untapped resource potential — such unoccupied hyperspace, a vacant niche? □

Nuclear polysomes
from J. R. Tata

CELL biologists often emphasise the intracellular segregation of transcription and translation between the nucleus and cytoplasm as a major distinguishing feature between eukaryotes and prokaryotes Every so often, however, fresh controversy is generated by reports that challenge the validity of this intracellular compartmentation of macromolecular synthesis by demon-

strating that nuclei can also synthesise proteins (for a review, see Kuehl, in *The Cell Nucleus*, edit by Busch, H., 3, 345, Academic Press, New York, 1974). Many such claims have had a short life since these are based on indirect evidence, or fail to identify a special class of proteins synthesised within the nucleus. Perhaps the most important reason for the controversy over whether or not the nucleus possesses a protein synthetic apparatus may reside in the ease with which isolated nuclei are contaminated with cytoplasmic polyribosomes (Penman, *J molec Biol*, 17, 117; 1966), particularly those associated with the perinuclear endoplasmic reticulum (Lewis and Tata, *J Cell Sci*, 13, 447, 1973).

Jo Alene Goidl and coworkers at the

Roche Institute in New Jersey have now managed to demonstrate polyribosome-like structures from isolated HeLa cell nuclei meticulously freed of contaminating cytoplasmic polysomes by detergent treatment (Goidl *et al.*, *J. biol. Chem*, **250**, 9198; 1975). Exposure of these nuclei to polyanions (heparin, RNA and particularly poly (U)), which are known to disrupt nuclear structure (Coffey *et al.*, *Adv. Enzyme Regnt*, **12**, 219; 1974), caused the release of particles of 200–300 A in diameter. These unique particles were shown, in a heterologous translation system derived from Ehrlich ascites cells, to comprise mRNA or precursors of mRNA associated with ribosomes and the complex itself was shown to be able to carry out translation. Goidl and her colleagues also found that poly (U) used for the disruption of nuclei was not associated with these nuclear polysomes; yet they were capable of polypeptide chain elongation but not initiation, as judged by effects of inhibitors of cell-free protein synthesis. These findings may have some relevance to those of Bachellerie *et al.* (*Eur. J Biochem.*, **58**, 327; 1975), who characterised transcription complexes of ribosomes and particles containing HnRNA still bound to chromatin derived from nuclei of ascites hepatoma and Chinese hamster ovary cells. The question of whether such complexes synthesise proteins within the nucleus or whether they are "packages" for transport of mRNA into the cytoplasm, as Harris (*Nucleus and Cytoplasm*, Clarendon Press, Oxford; 1974) suggested, is still open. Be that as it may, in view of the past controversy about protein synthesis by isolated nuclei, Goidl *et al.*, quite prudently, still do not state categorically that their polyribosomal material is exclusively nuclear but imply that if these complexes are of cytoplasmic origin, then their release from the nucleus somehow requires disruption of chromatin.

In a wider context, two questions concerning the capability of protein synthesis by nuclei have now to be considered. First, if they do have this function, do they make special classes of proteins? There are periodic but often unconfirmed reports of such special proteins exclusively made in the nucleus, but it is almost certain that the major nuclear proteins (histones, acidic chromosomal proteins, DNA and RNA polymerases) are synthesised in the cytoplasm. Second, what is the likely magnitude on a cellular basis, of protein synthetic activity in the nucleus? By isolating detergent-washed nuclei from sea urchin blastula cells, labelled *in vivo* with ³H-leucine, Allen and Wilt (*Expl Cell Res.*, **97**, 151;

1975) concluded that no more than 0 2% of the total cellular nascent polypeptides could be recovered with the nuclei. Perhaps this figure may be higher for nuclei or other cells, such as thymus or nucleated erythrocytes, but it is still likely to be quite low. Whatever the extent of protein synthetic activity of the nucleus. Goidl and her colleagues have certainly reopened, and with convincing evidence, an old controversy. Past critics will certainly find new reasons to disbelieve translation of any RNA within the nucleus. One has only to go back fifteen years to recall the controversy raging around protein and nucleic acid synthesis in mitochondria to draw a useful lesson and keep an open mind on this unsolved problem. □

Estimating maximum quake magnitudes

from Peter J. Smith

ACCORDING to a well known empirical formula, the number (N) of earthquakes per unit time exceeding any magnitude (M) is given by $\log N = a + bM$. Both a and b are usually described as positive constants, although they are not universally constant; a varies greatly from region to region and b, though generally more restricted, varies with region, focal depth range and in some areas even with magnitude. Irrespective of these variations, however, implicit in the general relationship is the existence of an upper limit on earthquake magnitude. If a and b are taken to be the averages for worldwide earthquakes, this limit turns out to be about 9.0.

It would appear from the work of Perkins (*Earthquake Inf. Bull.*, pp 18–23, July 1972), and others that this maximum magnitude may be established on the basis of worldwide earthquake statistics covering the period of only the past 50–70 yr, during which time it may safely be presumed that at least one event of roughly maximum magnitude has actually occurred (for example, the magnitude 8.9 earthquakes of Colombia in 1906 and Japan in 1933). Unfortunately, the establishment of a global upper magnitude is largely of academic interest. A more common practical problem (for example, in the field of earthquake engineering) is the assessment of the likely maximum magnitude of earthquakes within a restricted local region where the seismic statistics are but a depleted subset of the global total.

In local areas where earthquakes are clearly associated with faults, a very rough estimate of likely maximum magnitude along a given fault may be

made from curves of fault length against magnitude based on recent seismic experience. Unfortunately, however, the correlation between earthquake magnitude and surface rupture is poor and varies with fault type. In regions where the faults are less clear, the prediction of the upper limit is even more uncertain; it can only be assumed that the earthquake of highest magnitude ever recorded in the area could be repeated anywhere within it The drawback of such a method is obvious An earthquake of the highest possible magnitude for any given zone may not have been recorded in the zone in historic time. Moreover, the period covered by local seismic statistics may be quite insufficient to define an expected maximum magnitude on the basis of the formula involving a and b.

But how long a sampling period would be adequate? According to S. W Smith (*Geophys. Res Lett*, 3, 351; 1976), if the Earth's major seismic zones with a total length of about 80.000 km produce several maximum magnitude earthquakes in 50 yr, then 20.000 yr of seismic monitoring would be needed to give comparable statistics on a local scale of, say, 100 km. Needless to say, such long term monitoring is out of the question. On the other hand, it is quite feasible in principle to obtain fault displacement over a comparable period from the geological record. What is required, then, is some way in which, in the absence of an adequate seismic record, the geological record may be made to yield an estimate of maximum seismic magnitude.

The essential link between geological data and earthquake statistics, Smith proposes, is seismic moment. As defined in the dislocation theory of faulting, the seismic moment of an event is the product of rigidity, fault area and the average slip over the fault during the event. This relationship was exploited some years ago by Brune (*J geophys. Res*, 73, 777; 1968) who used it to estimate the total slip along major fault zones by summing the seismic moments of recorded earthquakes. Smith now reverses the process by using the geological record of total fault slip to determine the total historic seismic moment on a fault This total moment is then fed into an expression for maximum magnitude obtained by integrating the moments of all earthquakes along the fault up to the maximum magnitude.

Inevitably, such a process involves assumptions. One is the taking of an empirical relationship of the form $\log Y = c + dM$ between moment (Y) and magnitude (M). Another is the validity of the original N–M relationship. It must also be assumed that the

seismicity is a stationary process on a time scale of thousands of years and that during those years the maximum earthquake has occurred at least once. Finally, implicit in the method is the assumption that the observed geological displacement along the fault is due to earthquakes rather than creep, for any significant component of creep would lead to an overestimation of the maximum expected magnitude.

The need for these assumptions and natural deficiencies in the basic geological data combine to ensure that the method is less than perfect. On the other hand, as Smith points out, it does have the merit over existing techniques of making greater use of geological information. In any event, application of the method predicts maximum magnitudes of 8.2–8.4 for the first order branches (for example, the Calaveras fault) of the San Andreas fault system, 6.3–6.5 for lesser branches (for example, San Simeon) and 6.3 for still lesser branches (for example, West Huasna). Whatever the validity of these figures (compare magnitude 8.3 for the 1906 San Francisco shock) they are certainly more precisely defined than those obtained from fault length-magnitude curves. For a 200 km fault, for example, the conventional technique would only give an upper limit in the looser range 7.3–8.5. □

Poly(ADP-ribose)

from Mark Smulson and Sydney Shall

The fourth International Workshop on poly(ADP-ribose) was held in Hamburg on August 2–4, 1976, was sponsored by the Deutsche For-schungsgemeinschaft and organised by Professor Helmuth Hilz.

THE enzyme poly(ADP-ribose) polymerase requires DNA and catalyses the successive transfer of ADP-ribose units from NAD to histones and other proteins associated with chromatin, the net result being negatively charged, short polymers covalently attached to nuclear proteins.

The workshop concentrated on three main themes; possible biological roles for this modification, definition of the nature and chemistry of the protein acceptors of the polymer, and the purification and characterisation of the enzyme itself. The most exciting advance in the area was experiments suggesting that poly(ADP-ribose) cross-links chromosomal proteins. P. R. Stone and W. R. Kidwell (National Cancer Institute, Bethesda) reported that after incubation of HeLa cell nuclei with NAD, a dimer of histone H1 can be isolated containing one link-

ing chain of 15 ADP-ribose residues. Further evidence for this structure was provided in the previous week in a lecture at the International Congress of Biochemistry in Hamburg by G. Dixon (Calgary Medical School, Canada): he suggested either an inter-or intramolecular covalent linkage by way of poly(ADP-ribose) between glu-tamic acid residues near the amino terminal and carboxyl terminal ends of trout sperm histone H1. Since the con-centration of poly(ADP-ribose) in in-tact HeLa cells reaches a maximum at the S–G2 phase boundary, Kidwell sug-gested that the crosslinking property of poly(ADP-ribose) for histone H1 (and perhaps non-histone protein acceptors as well) might function to link widely spaced H1 molecules along internucleo-some regions and hence condense chromatin. This model was supported by the finding (M. Smulson, George-town University, Washington) that enzyme activity can be detected in internucleosome regions of chromatin and not on isolated nucleosomes.

Extensive purification of the enzyme has been accomplished independently in at least four laboratories. Okayama, Ueda and Hayaishi (Kyoto) have found during their 7,000-fold purifica-tion that an endogenous acceptor for ADP-ribose copurifies with the enzyme; and it may not be a simple protein. Histones decrease the K_m for NAD in their preparation. Confirmatory results were reported by K. Yoshihara (Nara Medical School, Japan). Both S. Shall (University of Sussex) and P. Mandel (Centre de Neurochimie du CNRS, Strasbourg) suggest the loss of an in-hibitor of the enzyme during their purifications. In addition, Shall and coworkers have estimated the K_i for a number of poly(ADP-ribose) poly-merase inhibitors which turn out to be also cyclic AMP phosphodiestrase in-hibitors, with higher affinity for the poly(ADP-ribose) polymerase, suggest-ing that some biological effects attri-buted to cyclic AMP from inhibitor studies, might really be due to poly-(ADP-ribose). Certain NAD analogues were reported to be incorporated into poly(ADP-ribose) chains (R. Suha-dolnik, Temple University).

Various new data on chromosomal protein acceptors for poly(ADP-ribose) were presented. M. G. Ord and L. A. Stocken (University of Oxford) find that histone H3 as well as H1 has ADP-ribose. Hilz and coworkers (Hamburg, Germany) have found heterogeneity both in the acceptors among non-histone proteins and in the sensitivity of the covalent linkage to cleavage. The proportion of monomer and poly-mer varies with changes in cellular proliferation rates. M. Miwa and T. Sugimura (National Cancer Centre, Tokyo) have been able to detect poly-

mer chains with equal (ADP-ribose) units but with different phosphate termini by acrylamide gel electro-phoresis.

One frustration has been the hetero-geneity in the "tentatively" reported covalent linkage of the first ADP-ribose to histones. The proposed link-ages include attachments from C-1 ribose to glutamyl carboxyl and threonyl hydroxyl by way of glycosidic bonds, to seryl phosphate by way of an ester bond or N-glycoside to arginine, and a possible Schiff base linkage. Much work clearly needs to be done in this area, but the heterogeneity of acceptors between histones and non-histone proteins suggests that vari-ous covalent attachment sites will ulti-mately be established.

The development of new ultrasensi-tive assays, including fluorometric determination (Mandel) and radio-immunoassays (Miwa and Sugimura; Bredehorst and Hilz; Kidwell) for quan-titation of poly(ADP-ribose) in cellular extracts, have produced substantial, but still far from definitive progress towards assigning a biological function to this fascinating chromosomal protein modification system. Reports at the workshop suggest that ADP-ribosyla-tion, like other nuclear protein modi-fications such as phosphorylation, probably has multiple functions all revolving around specific large or small structural pertubations of chromatin. Increases in enzyme activity are noted in SV40 transformation of cells (M. Miwa and T. Sugimura) for example; in induction of globin mRNA in Friend cells (E. Rastl, Ernst-Boehringer-Institut, Vienna) and an interesting correlation was described by A. Caplan (Case Western Reserve University, Cleveland) between intracellular NAD levels, poly(ADP-ribose) polymerase activity and the differentiation of mesenchymal cells either to muscle or cartilage.

Experimental approaches which make use of the effect of cytotoxic DNA-alkylating agents on poly(ADP-ribose) polymerase activity and *vice versa* also indicate that poly(ADP-ribose)–induced changes in chromatin structure may be important in repair of DNA damage. Fragmented sites seem to be a signal for increased *in vivo* activity of poly(ADP-ribose) poly-merase (groups at Georgetown and Sussex).

On the basis of data showing accu-mulation of poly(ADP-ribose) in mid-S phase and again in the G2 phase of the cell cycle (Kidwell) there was also speculation that chromatin repair and housekeeping must occur after the first peak of S phase, perhaps by way of polyADP-ribosylation relaxation of chromatin, and again in early G2 phase for cells to complete a normal cycle.

review article

Background of modern comet theory
Fred L. Whipple*

The modern understanding of comets dates from the publication in the early 1950s of three crucial ideas: that of a comet cloud around the Sun, that of the dirty-ice comet nucleus, and that of the "solar wind" to explain the comet tail. Starting from those three ideas, the observations of the past 25 years have led to the explanation of all the mysterious and sometimes spectacular phenomena associated with comets.

ANCIENT records indicate that extremely bright comets terrified almost everybody. Their erratic, unpredictable and mysterious activities seem to have touched off a basic human fear of the unknown, not just a fear of dangerous atmospheric objects which comets were assumed to be. This primitive fear, no doubt exploited by man's spiritual advisors throughout history, was still being exploited in this century. Entrepreneurs, for example, sold "comet pills" as preventative medicine against the noxious vapours from Halley's comet during its apparition in 1910. Chinese astronomers, incidentally, recorded Halley's great comet in 239 BC and probably as early as 467 BC[1].

Tycho Brahe of Denmark was the first to undermine the basis for this fear. He removed comets from the upper atmosphere and placed them in the sphere of modern scientific research by proving that the bright comet of 1577 moved in interplanetary space at a greater distance from Earth than the Moon. Sir Isaac Newton then applied gravitational theory to comets and calculated the first periodic orbit for a comet—that of 1680. Applying Newton's methods, Edmund Halley first predicted correctly the return of a comet, alas posthumously, when he identified the bright comet of 1682 as the return of comets seen in 1607 and 1531. His words: "therefore, if it should return according to our predictions about the year 1758 impartial posterity will not refuse to acknowledge that this was discovered by an Englishman." Hereby acknowledged!

Since about 1700, the discovery, the meticulous observing and the calculating of orbits for comets has been a major astronomical enterprise. Marsden's[2] *Catalogue of Cometary Orbits* lists 21 orbits in the seventeenth century; 63 in the eighteenth; 308 in the nineteenth; and 513 in the twentieth (until 1975). In all, the catalogue includes 964 apparitions of 625 individual comets of which 102 have periods less than ~150 yr. One must admire and be grateful for the patience, persistence and careful workmanship of the cometary astronomers who have given us so much invaluable basic information. But a knowledge of the precise orbits and appearance of many comets was only a necessary prelude to understanding their true nature. The phenomena of comets are produced by physical and chemical processes, which had to be ferreted out step by step. Some of these major steps are described in this paper.

Kepler, although he did not understand the orbital motion of comets, sought to explain earlier observations that comet tails point away from the Sun "by the supposition that a

tail is formed by rays of the Sun which penetrate the body of the comet and carry away with them some portion of its substance."[3]. He thereby anticipated the phenomenon of solar radiation pressure as a major factor in the formation of comet tails, although the phenomenon itself was not demonstrated theoretically until much later by Clark Maxwell, and in the laboratory by Lebedev in 1901. Bessel, in 1836, initiated the mathematical analysis of a solar repulsive force on particles ejected from comets and forced into their tails, although he looked on the force as electrical or magnetic. Bredikhin, in 1903, further developed and applied the theory to account for the observed highly curved dust tails. Theoreticians, however, remained frustrated in their attempts to explain motions in the great straight tails by means of solar radiation pressure alone. Accelerations exceeding a hundred times solar gravity, even on light ionised atoms or molecules, require a force that is much better coupled than solar radiation.

Schiaparelli, in 1866, made a major step in understanding comets when he identified the orbit of the Perseid meteor stream of August with that of Tuttle's comet of 1862, thus proving that comets lose solid bodies and therefore must contain them intrinsically. Two years earlier Donati made the first spectroscopic observations, a start towards the later identification of the bands and lines of radicals, atoms and ions and of the continuous spectrum reflected by dust. By 1911 Schwarzschild and Kron had identified the fundamental fluorescent process by which the band spectra are produced. Solar radiation is absorbed in ground energy levels of atoms or molecules, producing excitation. Fluorescence or reradiation then follows by cascading from high energy levels through various lower levels. Because of low space densities and dilute solar radiation the higher energy levels are erratically filled, depending on the intensity of the solar radiation at the specific wavelengths of transitions from the ground levels. Thus the relative intensities of lines in the band spectra are distorted from their laboratory counterparts. Swings'[4] demonstrated in 1941 that the variable Doppler effect of a comet's velocity with respect to the Sun changes the critical wavelengths absorbed from the solar spectrum by cometary particles. Irregularities in the spectra then produce variations in the cometary spectra so that the distorted bands change their appearance with time.

Thus in the 1940s it was recognised that bright comets such as Halley's near perihelion (0.59 AU: 1 AU=the Earth–Sun distance) lose the order of $10,000\,t\,d^{-1}$ of C_2 alone[5]. The total loss rate had to be increased by the other observed contributing radicals, such as CN, CH, CO, OH and NH, amounting altogether to a moderate fraction of a

* Address: Center for Astrophysics, Harvard College Observatory and Smithsonian Astrophysical Observatory, Cambridge, Massachusetts 02138.

ton per second! Estimates of the meteoroidal losses as evidenced by meteor streams were smaller but of comparable magnitude, while the spectra of meteors showed the generally abundant heavier elements Fe, Ca, Mg, Mn, Cr, Si, Ni, Al and Na. Meteorites, however, did not seem to be of cometary origin as no falls had been observed from cometary meteor streams.

Erratic variations in cometary brightnesses had always been known, and careful observations had shown that the relationship between intrinsic brightness and solar distance (r) varied greatly from comet to comet, the average relationship being $\sim r^{-3}$ to $\sim r^{-4}$. A few comets had disappeared while others had split into two or more distinct components accompanied by a "burst" of luminosity, usually to disappear later. For the Sun-grazing family, however, a major component usually persisted to a considerable distance from the Sun. Encke's comet had made more than fifty revolutions with a supposedly (but erroneously high) diminution of some ten times in brightness.

Most of these facts and phenomena fit qualitatively with Proctor's late nineteenth century concept of the comet nucleus as a sand bank or gravel bank. He pictured the fundamental particles as solid meteoroids from which absorbed gases are released by solar heating, the rate of gas desorption increasing rapidly with decreasing solar distance. The observed phenomena are evanescent, resulting from solar radiation acting in various ways on the gas and dust.

Attempts to define such a gravel bank quantitatively, however, led generally to increasing difficulties or contradictions. The nature of the dilemma can be seen qualitatively. One extreme is the nearly transparent gravel bank with negligible gravitational cohesion. The particles are all exposed to sunlight and must lose most of their gases on the first heating. Unless metres in dimension, they must be vaporised and entirely lost for the several Sun-grazing comets. Because each particle moves in its own orbit about the Sun, particles of different sizes will be forced into orbits of different periods by the Poynting–Robertson effect of solar radiation. Tus comets, especially periodic comets, should be elongated along their orbits if their nuclei are transparent gravel banks.

At the other extreme, the gravel-bank model is opaque near the centre and massive enough to hold particles gravitationally against solar tide-raising disruption. Because of orbital motions the particles will collide frequently at very low velocities and there is no reason to believe that the collisions will all be elastic. Thus a compact core will develop and become essentially asteroidal in character.

Intermediate gravel-bank models have been designed to meet some of the observational requirements only to stumble in explaining others. A possible hierarchy of such models to account for various types of comets is still no solution because even the fit of a special model to a specific comet is usually unsatisfactory.

Furthermore, a sinister persistent threat to the various gravel-bank models lay in Encke's (1823) discovery that the comet of shortest period was measurably decreasing in period, some 2 h in 3.3 yr. During the following century, this comet, which had been named after Encke, slowly reduced its rate of period decrease, that is, its deviation from gravitational motion. The popular postulate of a resisting medium between the planets, tempting as it may have been in the eighteenth century, became progressively less tenable in the nineteenth because no other supporting evidence could be found and because improved knowledge of interplanetary space impressed progressively lower limits on its possible density. The death knell for the idea sounded when two other periodic comets showed positive accelerations in their non-gravitational motions. A resisting medium can only reduce the dimensions of an orbit and thus the period. Increasing periods negate the possibility of a resisting medium. Conclusion: some comets must engender intrinsic

forces to change their periods, an idea suggested by Bessel[6] as early as 1836 and by Dubiago[7] in 1948, but without realistic physical mechanisms.

In spite of increasing detailed knowledge about comets and the abject failure of the gravel-bank model to fit the data quantitatively, the quantum jump in cometary theory was delayed until the middle of this century. Three explicit new ideas then revolutionised our concepts of comets The application and development of these ideas led to remarkable advances. These new theories are presented here in the order of their publication and are identified in terms of the cometary phenomena involved.

Oort's great comet cloud

In 1950 Oort[8] developed the theory of a great comet reservoir, or cloud about the Sun, providing a source of "new" comets to replenish the observable supply. Oort demonstrated that passing stars can perturb comets from huge orbits, extending out perhaps to 40–50,000 AU, into orbits with perihelion passages among the planets. Perturbations by the planets, particularly Jupiter, then eliminate more than half of such comets in successive passages, but disturb some into the short period orbits associated mostly with Jupiter. Oort thus defined specifically "The Home of the Comet"—a vague concept predating him by more than half a century. Although Opik[9] had long since shown that such a solar attached cloud is quasi-stable with respect to stellar perturbations, he had not specified the retrieval process that brings "new" comets on nearly parabolic orbits into the inner Solar System for the first time.

The dirty-ice comet nucleus

Whipple's[10] theory that the nucleus of a comet is a compact mass of ices with intermingling earthy materials formed a basis for understanding many aspects of comets, including (1) comet activity by way of the sublimation of ices by solar radiation, (2) loss of large masses of gas and solids from long-lived comets, (3) observed deviations of comets from Newtonian motions, (4) the origin of comets by the aggregation of cosmically-abundant low temperature condensates from typical interstellar or stellar gases.

The solar wind and ion tails

Biermann's[11] concept—that solar corpuscular radiation, now generally known as the solar wind, could produce the structural forms and high accelerations observed in the ion tails of comets—provided the key that opened the door to understanding the one most conspicuous phenomenon of comets. These long, nearly straight tails sometimes extend for more than 10^4 km and show accelerations up to 100 times or more of solar gravity As we have noted, the explanation—solar radiation—that previously had served semiquantitatively to account for dust tails, curving strongly backwards in a comet's orbital plane, proved quite inadequate when applied to ion tails.

These three new concepts were accepted relatively soon by most of the astronomical community because they promised to fill conspicuous lacunae in the theory of comets. All the major questions regarding the nature and phenomenology of comets could at last be approached by observers, theoreticians and celestial mechanicians on the basis of reasonable working hypotheses, to be subjected to the scientific rigour of checking and improvement. The full blossoming of cometary astronomy then emerged. The subsequent outstanding developments of space science, coupled with highly improved optical, infrared and radio sensors, added a wealth of new information that could be quantitatively integrated with older data.

Here I outline the development of my own ideas about the nature of comets. I first note my faith in a basic general principle to be applied in exploring the frontiers of any field in science. One is attempting to find the way through a

swampy morass of mutually conflicting observations, interpretations and theories. The principle: seize on a few "indisputable facts" that appear most relevant; momentarily ignore the remaining data. On these solid "facts" build conceptual structures or working hypotheses that are self-consistent, strongly rooted in the best evidence available. Then attempt to expand each working hypothesis by fitting in the successively weaker material. Rejection of material must be rigorously monitored. Is it irrelevant? Is it erroneous? Is it misinterpreted because of incomplete theory or because of an unnecessary or erroneous assumption, either tacit or explicit? If none of these, another working hypothesis should be investigated.

The general knowledge of comets available to me in the 1940s is summarised above. But I was highly conscious of three other "solid facts" that had been published but may not have been known or considered important by others who were thinking about comets. The first fact was the clear cut evidence I[12] had amassed from photographic meteor studies that Encke's comet had made not just about fifty revolutions but actually thousands of revolutions. The second fact was the evidence from the polarisation of the Zodiacal Light that interplanetary space at the Earth's solar distance contains less than 10^3 electrons cm^{-3} and, therefore, even fewer atomic nuclei[13]. The third fact was Opik's[9] demonstration that a cometary cloud could be quasi-stable about the Sun to a distance of several times 10^4 AU. The third fact left me with little concern about the replenishment of the shorter lived comets, because Opik's work, it seemed to me, had implied this likelihood.

The critical factor to me was the large quantity of matter that comets lose to space. If any comet can persist for a thousand or more revolutions, coming to 0.3 AU of the Sun at perihelion, it must contain or acquire a substantial quantity of gas and solids (cubic kilometres?). Conceivably a gravel-bank comet might persist if there were a gas source in space to refuel the solids by absorption. A back-of-the-envelope calculation suffices to show, however, that the known gas content of interplanetary space is woefully inadequate. Given a few km^2 effective area of the gravel bank, based on the brightness of comets at great solar distances, and even a 1,000-km s^{-1} radial velocity for the solar-emitted gas, the "refuelling" situation is hopeless.

Other implications of the gravel-bank theory were totally unsatisfactory to me. As mentioned above, a heirarchy of particle sizes would conspicuously spread the gravel-bank along its orbit in a thousand revolutions. Also I could never visualise a satisfactory process to split a gravel bank in the manner required to account for comet splitting, nor, indeed, a mechanism to produce comet bursts.

A dirty-ice model of the nucleus could, however, carry any specified reserve of solids and potential gas. It could lie dormant at great solar distances and become increasingly active as it approached the Sun. It could withstand the temporary heating experienced by the Sun-grazing comets and, indeed, split tidally to give birth to the family. It could account, at least qualitatively, for almost all of the many phenomena of comets. Furthermore, is was reasonable in terms of cometary origin as a low temperature condensate from typical solar or interstellar material. The most abundant compound-forming elements in a "solar mix", H, C, N and O provide the atoms in the radicals producing cometary fluorescence, while the heavier elements would certainly freeze out if the more volatile gases could. In principle, then, the basic difference between the conditions for the origin of the terrestrial planets and the comets become one of temperature.

At this stage of my thinking I felt that the icy conglomerate model was so obvious that it must already have been tacitly accepted by the major students of comets. There seemed to be little justification for publishing the idea unless some quantitative aspects could be developed. In a remark-

able treatise Hirn[14] had essentially demolished the idea of a resisting medium because of its resultant effect on comets' tails, and concluded that cometary gas would be frozen at aphelion to *"forme alors un assemblage de corps solides désagrégés."* Pol Swings, indeed, who was impressed by my evidence for the great age of Encke's comet, almost presented the icy model in 1948 (ref. 15). He concluded that the gas of a comet occurs by evaporation, not by desorption, but failed to develop the concept further, being constrained by the classical assumption that a comet nucleus consists of numerous small bodies and that breakage is important to produce activity. In retrospect it seems that this persistent assumption of a multibodied comet nucleus was the major obstacle to an earlier development of the icy concept. I was not so constrained because I realised that solids imbedded in a small icy body of low surface gravity would be blown out aerodynamically by sublimating gases. The novelty of this idea did not occur to me at the time and thus I abandoned the comet problem for a year or two.

I decided to publish the icy comet model while working on a theory (unpublished) of meteor drag in the atmosphere. I was attempting to include a term in the classical drag theory to allow for the jet action of vaporising meteoroidal material. Suddenly I realised that an icy comet nucleus should produce just such a jet action. Furthermore, any delay in the sublimation process for a rotating nucleus would produce a jet force component normal to the solar direction and thus accelerate or decelerate the orbital motion, depending on the sense of rotation. Here was a quantitative mechanism for explaining non-gravitational motions in comets with either positive or negative rates of period change. Rotation might be expected for any solid body in space, but certainly could be produced in an irregularly shaped icy nucleus. The integrated force vector of the jet action need not point precisely at the centre of gravity. Thus the model could explain comet splitting as a spinup phenomenon, as well as a tidal disruption.

A major problem of comets was and, to some extent still remains: the identity of stable "parent" molecules to be dissociated into the observed radicals. Not being a chemist I was content with the previously suggested H_2O, CH_4 methane- and NH_3 (ammonia) to account for OH, CH and NH, respectively, with CO_2 (carbon dioxide) or CO for CO. The radical CN was more difficult because the obvious C_2N_2 (cyanogen) is so active. I favoured HCN, or C_2H and N_2 requiring some chemical action to produce CN. The chemists were unhappy with these "non-equilibrium" chemical companions but I felt (hoped) the compounds might bed together at very low temperatures. The extremely low temperature (≤ 20 K), required to freeze out CH_4, CO or N_2 worried me more. This problem was resolved by Delsemme and Swings[16] in 1952 who suggested that the highly volatile CH_4 and others might be imbedded in H_2O snow as hydrates or clathrates. Their suggestion fits the observations well and has generally been accepted.

The most likely parent molecule should be H_2O because of its high heat of vaporisation. It should also be the most abundant. The luminosity variation of short period comets clearly indicated its presence. At a solar distance of 2.5–3 AU the vapour pressure of H_2O in sunlight becomes negligible as does the activity of most of these comets.

Calculations[10] based on the assumption of icy conglomerate nuclei with the compositions suggested above led immediately to reasonable jet forces and lags in emission for Encke's comet and others, requiring nuclei with radii of only a few km. The loss of matter needed to account for the non-gravitational forces was only a fraction of one per cent per revolution. For longer period comets the jet force radial towards the Sun should exceed the transverse lag component. This has since been demonstrated[17] as well as non-gravitational motions among most of the periodic comets[18].
Fig. 1 Comet Kohoutek, 1973XII, Dec. 25.9, 1973. *a*, Photograph, Comet and Asteroid Observatory, South Baldy, New Mexico. *b*, NASA Skylab photograph in far-ultraviolet hydrogen Lα radiation. Both photographs are on the same scale as is the Sun's disk (circle) at same projected distance.

The great loss of H_2O from comets to be expected from the icy model was explored by Biermann and Trefftz[19] in 1960, who predicted a resultant huge hydrogen cloud observable by its Lyman α-emission line in the far ultraviolet (at $\lambda = 1,416$ Å). The observations from space vehicles dramatically verified this prediction for Comet Bennett, 1970II (refs 19, 20). The hydrogen cloud about Comet Kohoutek, 1973XII, in Fig. 1 dwarfs our old ideas about the spatial extent of bright comets. The total loss of H_2O amounted to a significant fraction of a 1 km³, typical of brighter comets.

Even though Comet Kohoutek may have been a dud in the eyes of the public, it was a huge success scientifically because it was the best observed comet in all history. Radio observations in the millimetre range produced spectacular new results : the identification of hydrogen cyanide, HCN (ref. 22) and methyl cyanide, CH_3CN (ref. 23). Methane and ammonia still remained elusive but the H_2O positive ion was identified in the optical spectrum and atomic O and C in the far ultraviolet. The neutral H_2O molecule resisted discovery until Comet Bradfield, 1974III. Comet Kohoutek brought the theorists to recognise the complex possibilities of gas-phase chemistry in the head of a comet, which leaves uncertain the true identity of some parent molecules because some of the radicals may be split up or chemically changed in the cometary atmosphere.

The presence of chemically ill-mated carbon molecules and the apparent low abundance of CH_4 in Comet Kohoutek show clearly that comets are a mixture of low temperature compounds, not formed by slow cooling from a hot gas. Such carbon compounds are prevalent in interstellar gas so that their occurrence in comets suggests a similarity between comets and the interstellar medium. Most students of the subject believe that comets probably formed in the outer parts of the planetary system, but do not exclude direct contributions from the interstellar cloud that collapsed to form the Solar System, or even the bare possibility of comet accretion in fragmented interstellar clouds connected gravitationally with the Sun.

The brilliant dusty Comet West, 1975n, split into at least four components, giving us an intimate look at a discrete comet nucleus. Figure 2 presents five successive large scale photographs of the head made at the New Mexico State University with their 20-inch reflector. The components are behaving as would be expected for multibodied nuclei: they are separating! The relative velocities are small, however, only a few m s⁻¹. But more interesting are the brightness variations shown on these beautiful photographs. At times components D, B and C are as bright or brighter than componet A. From an analysis of the motions, Sekanina[24] finds that component A is the main body of the comet moving in nearly a gravitational orbit. Component D separated first on February 13 starting at zero relative velocity with a relative deceleration, $d = 2.85 \pm 0.03$ in units of 10^{-5} solar acceleration. Component B separated second with $d \sim 5$ and C third with $d \sim 40$, an order of magnitude greater deceleration than D and B. As Sekanina predicted, C was short lived, becoming unobservable after three weeks from its separation on March 5.

Note the remarkable paradox. Component C must surely have been very much smaller and less massive than component A because it disappeared rapidly and because it displayed a huge non-gravitational deceleration, indicating a very much larger area–mass ratio for jet action. Nevertheless, component C outshone component A on at least two occasions. An explanation of this phenomenon lies inherent in the icy comet model. Let us accept the concept that the interior of an active comet contains a significant fraction of materials much more volatile than water ice. The surface layers, vaporising in sunlight, must become stratified with non-volatile dirt on the surface, water ice below, and successively more volatile materials underneath. The rate of mass loss is tempered by the dirt and hard-to-vaporise water ice. An exposed inner surface, however, will become far more active because of the materials with low heats of vaporisation.

The key to our explanation now lies in the simplistic fact that a solid of any shape whatsoever, when broken in

two pieces, exposes identical interior surface areas for each piece. Thus the small piece of a split comet nucleus exposes as much new surface containing highly volative materials as does the large piece. In certain orientations with respect to the Sun it can produce more activity than the large piece and hence outshine it. Continued breakage of the smaller component undoubtedly adds to its activity, to its rapid demise, and to its high decelerating force by jet action. Thus Comet West demonstrated before our eyes one of the striking properties of a dirty-ice comet nucleus.

As to the cause of comet splitting, other than tidal disruption, we have no definite proof. Rapid rotation produced by asymmetric jet action with resultant spinup seems to provide a reasonable explanation. It is not yet certain whether the equatorial layers need be spun off against gravity or whether the weak gravity, perhaps reduced by rapid rotation, allows the underlying volatiles or pockets of volatiles to eject large volumes of surface. In any case, splitting begets more splitting as would be expected if rotation has a role. A body in space will eventually rotate about the axis with maximum moment of inertia, being in unstable rotation about other axes. Loss of material usually changes the distribution of inertia so that after a split, the body will seek a new axis of rotation and alter the internal forces. More splitting may be expected and is frequently observed.

Plasma tails present a fascinating complex problem area for theoretical study and, indeed, have become a kind of space laboratory for magnetohydrodynamics. When instrumented space probes finally reach comets, the cometary space laboratory will become a reality, to answer many of these physical problems, as well as those of gas-phase chemistry in comets and, most important, to tell us about the true composition and physical structure of comet nuclei. From space probes we can hope to pin-point the circumstances of cometary origin and their relation to other bodies in the Solar System, particularly the Earth. I am convinced that comets contributed significantly to the life-giving volatiles of the Earth and, indeed, would not be surprised to learn that material contributed by comets made possible our very existence on this planet.

Transitions in double-diffusive convection

Herbert E. Huppert

Department of Applied Mathematics and Theoretical Physics, Silver Street, Cambridge CB3 9EW, UK

The transitions of solutions of differential equations from one stability regime to another are of great current interest, both mathematical and physical, and there are conflicting hypotheses as to how such transitions occur. Here we present the results of an investigation of double-diffusive convection, which is important in oceanography, astrophysics and chemical engineering. The calculated transitions are found to be very different from those previously suggested.

MOST fluid motion is turbulent. One approach that has been used in investigating this form of motion is to examine the transitions undergone by an initially laminar flow in its evolution to a turbulent state. Landau[1] hypothesised that as some appropriate non-dimensional parameter, R, increases, a critical value is reached at which the particular time-independent laminar flow under investigation becomes unstable and equilibrates to a new time-dependent flow. At a larger critical value this flow itself becomes unstable and this process of transitions is envisaged to continue until the flow has become so complicated that it would be referred to as turbulent. An alternative hypothesis has been recently suggested by Ruelle and Takens[2], whereby after a relatively small number of transitions, a well defined value of R is reached at which the flow exhibits an abrupt transition to a far more complicated, random, and hence turbulent, motion. Since these are both abstract hypotheses, only a direct investigation of the governing equations of motion can decide if either of these descriptions is correct, or if a different set of transitions takes place. In an investigation of this sort, but motivated by biological considerations, May[3] recently determined the transitions that occur in a number of first-order nonlinear difference equations. He found that as the appropriate R increases through a sequence of critical values, the solution changes from consisting of one stable equilibrium point, through stable cycles of period 2^n ($n=1,2,\ldots$), and then, at a finite value of R, there is chaos, with slightly different initial conditions leading to solutions which diverge with time. We present here the results of explicit calculations of the transitions that occur in two-dimensional double-diffusive convection. The motion is governed by a set of coupled nonlinear partial differential equations and the transitions that occur are different in form from the three discussed above.

Double-diffusive convection

Double-diffusive convection is a generic term for the type of convection that occurs in fluids in which there are two components of different molecular diffusivities which contribute in an opposing sense to the vertical density gradient. For different sets of components, this form of convection has an important role in oceanography, astrophysics and chemical engineering[4]. Here we use the terminology of heat and salt, the components appropriate to oceanography. We restrict attention to the

Rayleigh–Bénard problem[4], where the fluid is considered to occupy the space between two infinite planes separated by a distance D, with the upper plane maintained at temperature T_0 and salinity S_0 and the lower plane maintained at temperature $T_0+\Delta T$ and salinity $S_0+\Delta S$ (ΔT, $\Delta S > 0$). We assume both planes to be stress free and perfect conductors of heat and salt, and restrict attention to two-dimensional motion, dependent only on one horizontal coordinate and the vertical coordinate. Expressing all lengths in units of D, time in units of D^2/κ_T (where κ_T is the thermal diffusivity) and representing the temperature T^* and salinity S^* by

$$T^* = T_0+\Delta T(1-z+T); \quad S^* = S_0+\Delta S(1-z+S)$$

we can write the governing Boussinesq equations of motion in terms of a stream function ψ as

$$\sigma^{-1}\nabla^2\partial_t\psi - \sigma^{-1}J(\psi,\nabla^2\psi) = -R\partial_x T + R_S\partial_x S + \nabla^4\psi$$
$$\partial_t T+\partial_x\psi - J(\psi,T) = \nabla^2 T$$
$$\partial_t S+\partial_x\psi - J(\psi,S) = \tau\nabla^2 S$$
$$\psi = \partial_{zz}^2\psi = T = S = 0 \quad (z = (0,1))$$

where

$$J(f,g) = \partial_x f\partial_z g - \partial_z f\partial_x g$$

Fig. 1 The results of linear stability analysis for $\sigma = 1$ and $\tau = 10^{-\frac{1}{2}}$. Overstability first occurs along $R = R_1$ and monotonic stability first occurs along $R = R_6$. Only the hatched region is stable to linear disturbances.
The four non-dimensional parameters appearing in these equations are: the Prandtl number $\sigma = \nu/\kappa_T$, where ν is the kinematic viscosity; the ratio of the diffusivities $\tau = \kappa_S/\kappa_T$, where κ_S, the saline diffusivity, is less than κ_T; the thermal Rayleigh number $R = \alpha g \Delta T D^3/\kappa_T \nu$, where is α the coefficient of thermal expansion, and g is the gravitational acceleration; and the saline Rayleigh number $R_S = \beta g \Delta S D^3/\kappa_T \nu$ where β is the saline analogue of α.

Stability

The criteria for the linear instability of these equations are obtained by neglecting the nonlinear Jacobian terms and representing the solutions in terms of the lowest normal modes with an exponential time dependence of the form $\exp(\omega t)$. The onset of overstability, defined by $\mathscr{R}(\omega) = 0$, first occurs for a value of R which we denote by R_1 and exchange of stabilities, defined by $\omega = 0$, first occurs for a value of R which we denote for convenience by R_6. In both cases the horizontal wavelength of the instability is $2^{3/2}$. In the $R-R_S$ plane the linear stability boundary is a combination of $R = R_1$ and $R = R_6$, as depicted in Fig. 1, which presents a summary of the linearised results for $\sigma = 1$ and $\tau = 10^{-1/2}$. For $R_S > R_{1n6}$, where R_{1n6} is the value of R_S at which $R_1 = R_6$, as R exceeds R_1 the conduction state $(\psi = T = S = 0)$ becomes unstable to an oscillatory mode. For $0 < R < R_{1n6}$ as R exceeds R_6 the conduction state becomes unstable to a monotonic mode.

We present here the form of the solutions of horizontal wavelength $2^{3/2}$ which emanate from the above linear transitions, or bifurcation points, as the degree of nonlinearity increases. An appropriate way to describe the resulting solutions is as a function of their amplitude. This is conveniently represented by either the thermal or saline Nusselt numbers evaluated by the lower boundary

$$N_T = 1 - \overline{\partial_z T}|_{z=0} \quad \text{and} \quad N_S = 1 - \overline{\partial_z S}|_{z=0}$$

where the overbar denotes a horizontal average, or by their respective temporal maxima, M_T and M_S. Since for most physical systems $R_S > R_{1n6}$ and this is conceptually the most interesting case, we concentrate on the latter regime and, principally by numerical integration of equations (1), map out the forms of equilibrium solutions in an $R-M_S$ plane in the manner depicted in Fig. 2. The discussion is in general terms; specific details and physical interpretations of the solutions will be published elsewhere (H. E. Huppert and D. R. Moore, in preparation).

The bifurcation point at R_1 can be either supercritical (R increases as M_T or M_S increases) or subcritical (R decreases as M_T or M_S increases). By the straightforward use of modified perturbation theory[5], a very lengthy relationship can be determined (H. E. Huppert and D. R. Moore, in preparation) which indicates, for fixed σ, τ and R_S, which of the two possibilities occurs. It is known from general theory[5] that solutions on branches emanating from subcritical bifurcations are unstable until the branch reaches a minimum value of R. Thereafter the branch continues with the amplitude of the associated time-dependent solutions increasing with increasing R. Supercritical branches are known to support stable solutions. A typical plot of N_T and N_S against time for a solution on a stable portion of the branch sufficiently close to R_1 is shown in Fig. 3a.

Increasing R

As R increases, this form of motion continues until R reaches a specific value, R_2 say. At $R = R_2$ the solution changes in form and develops a further structure as is indicated in the form of N_T or N_S as a function of time, as plotted in Fig. 3b. In both N_T and N_S there are four extrema, two maxima and two minima, per period, where the period is defined in the usual sense as the time between two identical states. In modern mathematical jargon, the solution for $R < R_2$ is on a sphere, while the solution

R389
Fig. 2 The stable oscillatory branch and the stable monotonic branch for $\sigma = 1$, $\tau = 10^{-\frac{1}{2}}$ and $R_S = 10^4$. For $R_2 < R < R_3$ the branch is drawn so as to show both local maxima. For $R_3 < R < R_4$ the wavy line indicates that the solution is non-periodic and no definite maximum can be assigned. The dots at $R = R_4$ and $R = R_5$ indicate the jumps in M_S which occur as the solution changes from the oscillatory branch to the monotonic branch.

for $R > R_2$ is on a torus, and the transition at $R = R_2$ is called a bifurcating torus[6]. This form of motion continues until $R = R_3$ say, at which value a transition to a disordered solution occurs. A typical plot of N_T and N_S against time for such a disordered solution is shown in Fig. 3c. Long computation runs have not revealed any discernable periodic structure in the solution. Such non-periodic solutions continue to exist for increasing R until, for $R = R_4$ say, the only equilibrium solutions are time independent. For some values of σ, τ and R_S the transition at R_4 occurs before the one at either R_2 or R_3.

For all $R > R_4$ all equilibrium solutions are independent of time. Time-independent motions are more efficient at transporting heat and salt than time-dependent motions and thus the Nusselt numbers undergo a discontinuous increase as the solution changes from being on the oscillatory branch to the monotonic branch, as indicated in Fig. 2. As R increases

Fig. 3 The thermal and saline Nusselt numbers as a function of time for $\sigma = 1$, $\tau = 10^{-\frac{1}{2}}$ and $R_S = 10^4$. a, $R_1 < R = 8,600 < R_2$; b, $R_2 < R = 9,800 < R_3$; and c, $R_3 < R = 11,000$. The horizontal line in the bottom right-hand portion of c, represents non-dimensional time.
beyond R_4 the effects of the salt field decrease, and for $R \gg R_4$ the equilibrium solutions approach those for $R_S = 0$, a situation which has been intensively investigated by Moore and Weiss[7].

Decreasing R

If R is gradually decreased from some value greater than R_4, the equilibrium monotonic solutions retrace the states that would have been obtained on increasing R from R_4; for each $R > R_4$ there is a unique stable equilibrium solution. If R is decreased below R_4, an equilibrium time-independent solution continues to exist, with decreasing amplitude, until $R = R_5$ say. Further decrease of R leads to a solution on the oscillatory branch already described, or if $R_5 < R_1$ to the null solution. Thus, as indicated in Fig. 2 there is hysteresis between the two different forms of solution.

The time-independent branch of solutions emanates from the bifurcation point at $R = R_6$, which modified perturbation theory shows to be subcritical if $R_S > R_{1n6}$. As mentioned previously, solutions on such a subcritical branch are unstable until the minimum value of R is attained. Thereafter the branch continues and solutions on it are stable, with the amplitude of the solution increasing with increasing R.

If $R_S < R_{1n6}$ only time-independent equilibrium solutions are possible. For sufficiently small R_S the bifurcation at R_6 is supercritical, otherwise it is subcritical (H. E. Huppert and D. R. Moore, in preparation).

Conclusion

To summarise, in the most general case, as R increases there is a transition from the conduction state to an oscillatory motion (Fig. 3*a*), followed by a transition to a more complicated form of oscillatory motion (Fig. 3*b*), followed by a transition to a non-periodic, random state (Fig. 3*c*), followed by a transition to steady motion. Hence by increasing R it is possible in this situation to suppress disordered motions. For some values of σ, τ and R_S a sufficiently large disturbance can cause a transition directly from the conduction state to the steady state, while for other values of σ, τ and R_S only some of the intermediate transitions are omitted.

I thank Dr D. R. Moore, who wrote the numerical program used here, Dr Joyce Wheeler, who helped with the computations and preparation of the graphical output, and Professor R. M. May and Dr D. P. McKenzie for critical comments. This research was supported by the British Admiralty.

Stratified waters as a key to the past

Egon T. Degens

Laboratorium für Sedimentforschung, Mineralogisch-Petrographisches, Institut der Universität Heidelberg, Berliner Strasse 19, 6900 Heidelberg, FRG

Density stratification in lakes and oceans generate anoxic conditions below the pycnocline, and sediment facies mirror this development. A comparison of modern sediments deposited in stratified and non-stratified waters with sediments formed since the Cambrian reveals that the ancient sea has been stratified a number of times.

THE world ocean is fully oxygenated except for some local areas in regions of upwelling or stagnation. Oxygenation is related to modern climates, that is thermo- and haloclines, which can inhibit the mixing of water masses between stratified layers but which are only temporarily stable. Furthermore, cold polar surface water sinks and moves towards the equatorial abyssal plains. These and other climate-controlled physical factors turn over the ocean's water in a matter of a few hundred to a few thousand years. At this rate, molecular oxygen is recharged much faster in the deep sea than it is consumed by the oxidation of organic matter at greater water depths.

During prolonged warmer climatic stages or when land-locked seas develop, thermo- or haloclines may become so stabilised that they only move up and down in response to seasonal changes, tectonic activities, or some other major perturbations in the environment; but they rarely break up entirely. In such conditions molecular oxygen will remain abundant in the euphotic zone but will gradually drop to zero below the density boundary. This will cause the development of a euxinic environment in which no higher forms of life can exist and molecular oxygen is replaced by hydrogen sulphide.

It is important to know what happens to the strata when this situation arises because such information is crucial to the task of explaining the origin of euxinic sediments, which are so plentiful in the stratigraphic record. Unfortunately, comparative studies between shallow and deep-water habitats are hindered because most of the marine sediments exposed on continents are of shallow-water origin and suites of abyssal sediments have only recently become available through the Deep Sea Drilling Project.

A significant aspect of this problem which has received little attention in the past concerns a possible feedback mechanism between oxidising and reducing environments which may result in the formation of specific sediment types.

We will focus attention here on the feedback question by examining sediments of the same ages and geological settings which differ only in that one group has formed below and the other above a well defined thermo-halocline. The sediments are from cores from the Black Sea and some deep East African rift lakes and they represent continuous sections through parts of the Holocene and Pleistocene. A detailed examination of a thermo-halocline, oscillating through time, will allow us to follow in slow motion the impact of the reducing on the oxidising environment and vice versa.

Phase boundaries

An heuristic theorem implies that physicochemical phenomena established at the boundary between two different states characterise these two states. In the present context the theorem implies that the physicochemical properties of the reducing and oxidising environments are 'written' on the boundary layer, that is, the thermo-halocline. We will now examine this interface.

Mechanism and rate of molecular exchange across a well
Fig. 1 Scanning electron micrographs of chemically precipitated calcites, sedimented above O_2–H_2S interface (*a*), and below interface (*b*). Size of individual crystals ~ 5–10 μm.

developed thermo-halocline have been studied thoroughly[1-3]. Vertical advection and diffusion will move deep water through the density boundary to the surface layer. For the main pycnocline in the Black Sea this results in a vertical eddy-diffusion coefficient of ~ 0.014 cm² s^{-1} (refs 2 and 3). From this value one can readily calculate the net upward flux of dissolved species such as iron, manganese, or hydrogen sulphide. Against the upward advective gradient there is a downward diffusion gradient of oxygen. These two opposing fluxes will generate a wide range in redox potentials within a narrow segment of the water column. Some elements and minerals will respond to this Eh gradient by becoming reduced or oxidised, and precipitated or dissolved, respectively. In turn, minerals can form at one point, but by sinking through an Eh gradient they may

redissolve. Depending on the speed of this reaction and the general hydrographic setting, the process of precipitation and dissolution can continue again and again and lead to substantial concentrations of certain elements and minerals close to the pycnocline.

Models using a constant eddy-diffusion coefficient for the vertical transfer of passive properties in a continuously layered medium[4,5] are only applicable for periods of hours and days because density boundaries tend to rise and fall and many other physical perturbations do exist[6-9]. If the interface is lowered rapidly, an almost spasmodic mineralisation of the upper layer will take place resulting in massive precipitation of a series of minerals. In contrast, a rise of the interface will dissolve the same minerals. Figure 1 shows calcite which has precipitated in the upper layer. In Fig. 1*a* the calcite remained in the surface layer, whereas in Fig. 1*b* it sank into the anoxic water. It is of note that all carbonates including dolomite and siderite will eventually dissolve if exposed to highly reducing environments.

East African rift lakes

The deep rift lakes of East Africa—Tanganyika, Malawi and Kivu—are thermally stratified. The perennial thermocline in Lake Tanganyika lies at ~ 100 m but is somewhat deeper and much more variable in Lake Malawi. Lake Kivu has a stable thermo-haline density structure with an interface at ~ 70 m (ref. 10). The position and nature of the density boundary influence the occurrence of distinct mineral and chemical facies observed in sediment cores of the three lakes[10-13]. Most notably affected by the position of the interface is the distribution of Fe-oxides, Fe-silicates, Fe-phosphates, Fe-sulphides, Mn-siderites and a series of Ca- and Ca–Mg-carbonates. In the following, we will examine sediments from deep (~ 500 m) and shallow (~ 50 m) parts of Lake Kivu that were deposited during the past 10,000–14,000 yr.

The impact of an oscillating stratification is illustrated by the distribution of manganese and related facies in a core from the central basin (see Fig. 2). The observed Mn^{2+} oscillations are interpreted as resulting from the following processes[14]. Thermal stratification allows Mn^{2+} and Fe^{2+} to accumulate in the water of relatively low pH below the thermocline. Vertical advection and diffusion transfer both ions through the interface where they instantaneously precipitate as manganosiderite. The newly formed mineral phase sinks back into deep water, dissolves, and the cycle starts over again. Its incorporation into the sediments will only be possible near the thermocline. The manganosiderite in Lake Kivu occurs, however, as discrete layers rather than as a mixture with the regular detritus. This suggests a more powerful transfer mechanism than advective eddy-diffusion: the rapid lowering of the thermocline and a resultant massive precipitation of the manganosiderite. Fluctuations in Mn^{2+} content shown in Fig. 2 reflect oscillations of the thermocline which shifted the area of manganosiderite deposition away from or back towards the location of the core site. High water stands are indicated by the emergence of sulphides and specific diatom assemblages in an organic-rich facies free of carbonates[14,15].

The profile continues in Fig. 3. This time, however, carbonate and organic carbon serve as indicators for the oscillating O_2–H_2S boundary[10]. Carbonate precipitation starts with high Mg-calcites and the percentage of $MgCO_3$ in solid solution is indicated numerically. At $CaCO_3$ concentrations > 10%, aragonite occurs. A change in mineralogy from Mg-calcite to aragonite reflects an increase in the Mg–Ca ratio in the lake water[13] which can best be explained by progressive evaporation which rapidly will lower both the interface and the water level and enforce lime extraction. The emergence of carbonate-free sapropels signals meromixis. Surface waters have pH values between 8 and 10 but as the pH drops below 7 the waters become anoxic. Carbonate particles falling into the deep water redissolve, whereas those that settle in shallow areas above the pycnocline remain intact and form thick sediment sections. Changes of the Mg–Ca ratio in the lake water will

Fig. 2 Distribution of manganese in Kivu sediments deposited during the time interval between 13,700 and 11,000 yr BP. Mineral facies and reconstructed thermocline oscillations are shown. High water stands are indicated by the emergence of sulphides and specific diatom assemblages[14,15].

established ecosystem. Whole populations can be exterminated; others can be pushed into restricted ecological niches from where they may perhaps reoccupy their former territory should the habitat change back to its former condition. Some species may adapt to the new environmental circumstances, whereas others may take advantage of the new situation and become dominant. In addition, some new species may evolve.

Lake Tanganyika, which has had a series of oscillating thermoclines and water levels[19-22], is a good test case for the evolution of species in a closed system. A large number of endemic genera and species is present in the modern lake[23], especially fish. When counted in 1960 (ref. 24), *Cichlidae* alone numbered no less than 133 species from 38 genera. Another point of interest is the striking resemblance of a great variety of present-day snails to certain marine forms that became extinct in the Jurassic[25,26]. All this has to be viewed against a background of a lake which formed in Miocene time and has never been open to the sea. In conclusion, the antiquity of Lake Tanganyika is mainly responsible for the evolutionary diversification, but temporal variability in lake levels, water chemistry, and stratification are considered dominant factors in triggering this development[14,15].

Black Sea

Much has been learned about the recent history of the Black Sea through a R/V Atlantis research cruise conducted by the Woods Hole Oceanographic Institution in spring 1969 (ref. 27). A topic of special significance for our work is the evolution of anoxic conditions during the Holocene[28].

Each gram-atom of carbon in plankton requires 1.3 mol of oxygen for its oxidation[29]. Since the amount of organic matter that falls through the O_2–H_2S interface is fairly well known[30], the 'decay' constant of the oxygen reservoir can be calculated[28]. From this number, the upward progression of the O_2–H_2S interface can be derived. Calculations show that the thermohaline boundary requires ~ 3,000 yr to rise from the 2,200-m-deep abyssal plain to a water depth of 500 m. Varve-counting techniques substantiate these findings[31] and indicate that finely laminated sapropels began to occur on the basin slope at a depth of 470 m almost 2,300 yr after they first appeared on the bottom of the Black Sea basin.

The sapropel facies is low in carbonates and many grains show corrosional features of the kind shown in Fig. 4. Of special note is the sapropel facies in a core from a water depth of 470 m which rests on a massive calcareous mud and is

determine the carbonate mineralogy[13,16]. Calcite, Mg-calcite, aragonite, protodolomite and monohydrocalcite generate cyclic patterns in the shallow basins of Lake Kivu, while at the same time a thin sapropel facies forms in the deep anoxic basin of the lake. Similar relationships exist in Lake Tanganyika[11,13].

The impact of an oscillating density boundary or a 'catastrophic' overturn is registered by the established fauna and flora. For instance in Lake Kivu the fish fauna is depauperate, chaoborids are absent and the molluscs, especially pelecypods, have suffered recent extinctions, judging from the abundance of shells of species which are no longer extant in the lake[15,17]. Particularly illuminating is the distribution pattern of diatoms over the past 14,000 yr (refs 14, 15 and 18). *Stephanodiscus astrea* declines almost linearly from ~ 90% of the total diatom population at ~ 14,000 yr BP to 0 at ~ 5,000 yr BP. Similarly, *Nitzschia fonticula* disappears at ~ 5,000 yr BP. Only one species, *Nitzschia spiculum*, crosses this boundary and is joined by newly emerging diatom species. These and related observations strongly suggest that changes in water chemistry introduced by a fluctuating interface can severely disturb the

Fig. 3 Distribution of $CaCO_3$ and organic carbon in Kivu sediments deposited during the past 11,000 yr (continuation of profile shown in Fig. 2). Numbers on carbonate curve represent the mole percentage of $MgCO_3$ present in high Mg-calcite; water depth: 473 m (ref. 10).
characterised by intercalations of very fine authigenic carbonate laminae up to 2 mm thick at the base of the sapropel but becoming finer and eventually disappearing towards the top of the sapropel layer. All these observations fit the general pattern described for Kivu sediments, and therefore indicate the same mechanism of formation.

Present—a key to the past

We have studied stratified waters in numerous environments for more than ten years[10–15,27,31,32]. It never occurred to us, however, that the results of these studies could significantly alter established concepts in geology. In other words, the subject was looked at more as an interesting anomaly rather than as a feature of global significance.

This outlook changed when we described sediment cores from the Deep Sea Drilling Project's Leg 42 B obtained by the Glomar Challenger in the Black Sea during May–June 1975. In three cores from the euxinic abyssal plain (core length 624.5 m) the basin apron (core length 1,073.5 m) and the basin slope (core length 503.5 m) a kind of textbook profile emerged consisting of successions of (1) shallow- and deep-water facies, (2) flysch and molasse cycles, (3) oxidising and reducing sediments, (4) clastic and chemical deposits, and (5) freshwater–brackish–marine series. Most striking is the distribution of authigenic carbonates. In going from the shallow to the deep basin, a typical facies succession is dolomite–aragonite–high magnesium calcite–calcite–siderite–carbonate–free sapropels. In view of these results, we will briefly compare present and past common sediment facies of the open marine environment. Since authigenic carbonates appear to be excellent environmental indicators, we will use them as tools in our comparison.

In modern marine environments, the chemical precipitation of calcium carbonates or dolomites is virtually nil. Recent marine carbonates are principally biological in origin. Calcitic foram and coccolith oozes cover wide parts of the deep sea and coral reefs, and coquina are found in some shallow-water environments. The distribution of calcareous oozes is controlled by the local carbonate compensation depth and a few other critical factors determining rates of dissolution[33]. In contrast, sand and clay are the typical facies in modern shallow-water deposits.

The stratigraphic record, from the Cambrian on, indicates an almost reversed situation. Hundreds of metres of shallow-water carbonates, distributed over extensive areas, are frequently encountered. Sedimentary cycles measuring not more than a few centimetres or metres can be traced over wide distances. On the other hand, an ordinary geosyncline commonly starts with a massive graywacke facies or a black shale facies free of carbonates. Judging by their physical appearance and chemistry, these sediments formed at great water depths and under anoxic conditions. In conclusion, sediment facies in the Black Sea and some East African rift lakes have many characteristics in common with ancient marine sediments, whereas sediment facies in the present ocean show little resemblance to the past record. These findings have interesting consequences because they suggest that the former ocean looked much like the present Black Sea. Two simple graphs will summarise the most critical points.

In the modern fully oxygenated ocean, sands and clays are deposited in the shallow sea (Fig. 5a). On stratification of the water, anoxic conditions develop below the interface and euxinic sediments form in the H_2S zone, whereas carbonates may develop in the oxic zone (Fig. 5b). It is essential to know that these two contrasting environments not only differ in oxygen and hydrogen sulphide but in a number of other chemical ingredients. As a common rule the anoxic waters are enriched in (1) mineral nutrients such as nitrate, phosphate, ammonia and silica, (2) some common elements, and (3) dissolved gases.

Lowering of the interface (Fig. 5c) will result in the transfer of dissolved chemical species into the upper layer. Primary productivity will be stimulated and carbonates will precipitate with the Mg–Ca ratio in the water phase controlling the carbonate
Fig. 4 Scanning electron micrographs of chemically precipitated aragonites buried below the O_2–H_2S interface. Note dissolution features similar to Fig. 1b. Size of aragonite grains ~ 20 µm.

mineralogy. An upward progression of the interface (Fig. 5d) will extend euxinic conditions to shallower parts of a basin, with established benthic communities becoming extinct, and carbonates starting to dissolve because the level of carbonate compensation in time will be identical with the level of the O_2–H_2S interface. As a function of climatic variation and constant reshaping of marine basins by tectonic or erosional forces, all transitions between a fully oxygenated and an anoxic sea are conceivable.

Sediment facies in the shallow water environment will mirror these events through distinct cycles and fossil assemblages. At O_2 times, the sediment distribution in the deep sea will resemble that of today, whereas at H_2S times, sapropels will occur, and calcareous oozes and marls will show pulses of dissolution. This process can go so far that a hiatus will develop and the dissolved chemical species will accumulate in the deep waters. Submarine volcanic activity and rifting will enhance these actions. It is of note that brines can accumulate in the deepest part of a basin. Upwelling or overturning of water masses will cause the release of these substances, and phosphorites, carbonates, and Fe–Mn oxides and hydroxides are a few of the major phases that may come into existence.

A graph (Fig. 6) shows schematically the pathway of four critical elements through geological time. The modern concentration level for each of the four elements in the deep sea is shown at the far right. The main features are as follows:

(1) Fe^{2+} becomes oxidised in the euphotic zone. Lowering of the O_2–H_2S interface will release Fe^{2+} to the upper layer causing the formation of siderite, a series of Fe-oxides and hydroxides, and Fe-silicates[34]. In the anoxic sea, Fe^{2+} is extracted as sulphide or silicate (for example, chlorite). Towards the end of the Precambrian, the ocean water turned over, fully oxygenating the deep sea for the first time, but went back to the anoxic state during the Silurian. This sequence is repeated several times throughout geological time.

Fig. 5 Formation and evolution of stratified waters (see text).
(2) In the Precambrian, the water is nearly saturated with silica below the interface. When released to the upper layer it precipitates on evaporation in shallow-water environments as amorphous silica. Biogenic silica extraction is the dominant release mechanism in more recent times.

(3) Mg^{2+} is extracted in the deep and shallow sea as silicate. Conditions for dolomite formation gradually develop and massive primary dolomite formation proceeds during the Palaeozoic and Mesozoic.

(4) Ca-carbonate deposition is dependent on the Mg–Ca ratio in the water phase[16]. Aragonite is the principal $CaCO_3$ species at the start of carbonate extraction, and high Mg-calcite, and eventually calcite, follow. Because of the instability of aragonite and high Mg-calcite, recrystallisation in the direction of hard dolomites and limestones is commonly observed in the older strata. In contrast, sediments composed of calcitic forams and/or coccoliths have a tendency to remain unindurated.

Conclusions

The highlight of the present study is the observation that permanently stratified modern marine and freshwater basins induce carbonate precipitation in the upper layer and carbonate dissolution in the anoxic deeper water. Vertical advection and diffusion will recycle dissolved chemical species back into the surface layer; however, a more substantial mineralisation of the euphotic zone is achieved by lowering the O_2–H_2S interface. This will promote massive carbonate precipitation. As a result sediments above a density boundary get rich in carbonates while those beneath have little or none. Because climate and/or geological settings change, thermo- and haloclines move up and down the water column or break up entirely, disrupting established ecosystems. The sediment record will reflect these incidents in the form of distinct cycles, facies, fossil assemblages, or hiatus.

Hutton's principle of uniformity of process, which holds that the present is the key to the past, gets an unexpected tenor. The well mixed oxygenated ocean of today seems not to be the model environment for the past 600 Myr. Instead, we are dealing with a sea which alternates between two opposing states: stratified and non-stratified. Depending on local or regional hydrographic settings, which may effect deep-water circulation and the hydrodynamics of water movement vertically and horizontally, one may encounter all sorts of transitions. At present, some areas in the open ocean are already anaerobic, and indicate the delicate balance between the oxic and anoxic states. All these findings lead us to conclude that a number of former interpretations regarding the origin of sedimentary cycles, the history of the oceans, and the workings of evolution have to be re-examined.

Fig. 6 Chemical evolution curves of Fe^{2+}, Si^{4+}, Mg^{2+}, and Ca^{2+} levels in the deep sea (schematic). The Fe^{2+} content in the upper layer drops to zero early in the Precambrian as soon as O_2-generation reaches a critical level.

Similarities and differences in the structure of X and Y chromosome rRNA genes of *Drosophila*

Kenneth D. Tartof
Institute for Cancer Research, Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111

Igor B. Dawid
Department of Embryology, Carnegie Institution of Washington, Baltimore, Maryland 21210

In Drosophila melanogaster, *the rRNA genes (rDNA) are clustered at single sites on two non-homologous chromosomes, the X and Y. Examination of the structure of X and Y rDNAs with restriction endonucleases reveals that the X rDNA contains repeating units not present in the Y. Such obervations, as well as genetic evidence, illustrate difficulties with the hypothesis that recombination is the predominant mechanism preserving similarities between these two clusters maintained on different chromosomes. This raises the possibility that selection pressure has a significant role in maintaining the parallel evolution of these two separate but homologous redundant gene clusters.*

In the fruit fly, *Drosophila melanogaster*, there is one nucleolus organiser (*NO*) on the X chromosome and one on the Y. At each *NO*, there are 200–250 tandemly arranged ribosomal RNA genes (rDNA)[1,2]. Although these genes reside on non-homologous chromosomes, the 18S and 28S RNA molecules transcribed from either the X or Y rDNA have very similar, and probably identical, primary sequences as revealed by fingerprinting experiments.[3] Furthermore, in the wild-type *D. melanogaster* male, which is genotypically XY, there is no meiotic recombination[4] though mitotic recombination occurs in both both sexes[5]. Thus not only are the rRNA genes located on non-homologous chromosomes but they also seem to be genetically isolated from one another by virtue of the absence of meiotic recombination.

Attempts to elucidate the detailed molecular structure of *Drosophila* rDNA by electron microscopic analysis of actively transcribing clusters of rRNA genes have produced conflicting results. Hamkalo *et al.*[6] found a very heterogeneous rDNA unit repeat length when embryonic material was used. Using similar techniques, Laird and Chooi (personal communication) have found that two length classes of rDNA repeats exist, both of which occur on the X *NO*, but only the shorter one was observed on the Y *NO*. Observations on rDNA fragments produced by the restriction endonuclease *Eco*RI and cloned in *Escherichia coli* revealed two distinct size classes of repeating units, one 17 kb (kilobases or kilobase pairs)[7] and the other, 11–12 kb (D. M. Glover and D. S. Hogness, personal communication). We report here the distribution of these size classes on the X and Y *NO*. Our results define the restriction endonuclease products of the X and Y rDNA, and demonstrate that both *NOs* are similar with respect to one major class of repeating

elements but differ decisively in their content of another class of repeats.

Restriction endonuclease analysis of X and Y chromosome rDNA

On treatment of unfractionated DNA of appropriate genetic origin with *Eco*RI the fragments were separated by Agarose gel electrophoresis and transferred to nitrocellulose filters according to the method of Southern[8]. The filter-bound fragments were hybridised to radioactively-labelled rRNA and finally made visible by autoradiography. Figure 1*a* shows the results of a series of experiments in which females (X/X) from two different wild-type strains (Ore-R and Lausanne) and males carrying only the Y chromosome *NO* are compared. It is obvious that the X chromosome contains both 17- and 11-kb segments while the Y contains the 11-kb but not the 17-kb fragment. In addition to these bands, two components of about 7.4 kb and 5.4 kb occur in both X and Y *NOs*. A mixture of X and Y DNA digested with *Eco*RI also displays these four bands, indicating that there is no apparent difference in the size of *Eco*RI fragments derived from X or Y chromosomes. When purified rDNA is digested with *Eco*RI there are, in addition to the predominant 17-, 11-, 7- and 5-kb size classes, minor fragment classes of intermediate length, some of which can be seen as bands in Fig. 1*b*. Somewhat similar length heterogeneities have been observed among *Xenopus* rDNA repeats[12].

From mapping studies it is known that the 11-kb and 17-kb fragments represent complete repeating units of the rDNA, which are distinguishable by the insertion of an additional spacer sequence within the 28S gene region (Glover and Hogness, personal communication; unpublished results of P. K. Wellauer and I.B.D.). The nature of the shorter 5- 7-kb fragments is not yet analysed, but it seems likely that they arise from the presence of additional *Eco*RI sites in a fraction of the repeating units. The other minor bands are due to additional *Eco*RI sites and to the length heterogeneity in the repeating unit.

The difference between the X and Y *NOs* can be demonstrated by other means. The restriction enzyme from *Serratia marscencens, Sma*I, yields a different fragment pattern from the two types of rDNA (Fig. 2). Y chromosome rDNA yields one fragment about 8.5 kb long and a second fragment 2.8 kb long, both of which hybridise to 28S and 18S RNA. *Sma*I digestion of X rDNA, however, produces a further fragment of 2.2 kb which hybridises with 28S but not with 18S RNA (Fig. 2). Another fragment of 2.3 kb can be seen in the ethidium bromide stained pattern obtained with rDNA purified from a mixture of males and
Fig. 1 *Eco*RI restriction pattern of *Drosophila* rDNA. The enzyme was prepared according to Greene *et al.*[9]. DNA of the indicated genotype was extracted, digested with *Eco*RI endonuclease and subjected to electrophoresis in 1% Agarose for 4 h at 100 V. The DNA fragments were transferred to a nitrocellulose filter[7] which was then hybridised to ^{125}I-labelled rRNA, 5×10^7 c.p.m. μg^{-1}, for 24 h in $2 \times$SSC at 60 °C. The filter was treated with RNase (30 μg ml^{-1}) at 37 °C for 60 min, dried and finally exposed to X-ray film for 5–10 d. The size of each fragment class is indicated in kb and was determined using *Eco*RI-treated λ DNA as the standard[10]. *a*, Ore-R wild-type female, Lausanne wild-type female, Ore-R female + male, and *sc⁴–sc⁸/Y* (Ore-R) male (*sc⁴–sc⁸* designates an X chromosome that is deficient for its *NO*, see ref. 11); *b*, purified rDNA from a mixture of males and females that has been digested with *Eco*RI with the resulting fragments separated by electrophoresis and then stained with ethidium bromide.

females, but it does not hybridise with rRNA and does not appear in the autoradiogram as do the other fragments. Thus the analysis with *Sma*I again confirms the presence of a structural difference between X and Y chromosome rDNA.

Fragment patterns of rDNA from *bobbed* mutants

To gain some insight into the relative interspersion of 17- and 11-kb units among each other we also analysed the fragment pattern obtained with *Eco*RI, using rDNA from four independently isolated X chromosome *bobbed* mutations. These mutations are deleted for 50–60% of their rDNA. If the NO consists principally of clusters of 17- and 11-kb units segregated from each other, then mutants deleted for 50% of their rDNA would be expected to be under represented for one class of the repeated units. Figure 2*b* shows that the rDNA in these mutants contains both the 17- and 11-kb size classes and that they are in roughly the same proportion to each other as in the wild type. Similar results have been obtained with six other independently

derived *bobbed* mutants. Because all these *bobbed* mutants arose by the deletion of half the rDNA repeats from an original *NO* and because each deletion arose independently, the results argue for interspersion of 11-kb and 17-kb repeat lengths. It is interesting that conspicuous length heterogeneity also occurs in the rDNA of most *bb* mutants (except *bb⁶*). The *bb⁸¹* mutant is actually a doublet in the 11-kb region. One band is 11 kb, the other 10 kb. *bb³* is extremely heterogeneous in the range 11 to 9 kb, revealing no discrete size class at the resolution of our gel, while *bb⁴* contains bands at 11 and 9 kb and many smaller bands. Such extensive heterogeneity has been observed consistently among *bobbed* mutants. In wild-type rDNA length heterogeneity does exist, but most repeating units occur as the 11- and 17-kb size classes (Fig. 1*b*). One possible explanation for this heterogeneity is that *bobbed* mutants result in the preferential retention of some minor size classes during deletion of predominantly 11- and 17-kb repeats. The heterogeneity of lengths of *Eco*RI fragments in *bb⁴*, however, are so extensive that they cannot be explained in this way and we must consider additional mechanisms for generating such variations. Perhaps this length heterogeneity is a consequence of the event that initially generated the *bb⁴* partial deletion.

Fig. 2 Fragments obtained from *Drosophila* rDNA with *Sma*I. The restriction enzyme was purified and used according to C. Mulder (personal communication). Fragments were separated and hybridised as described for Fig. 1. The stained pattern (ethidium bromide, 1 μg ml^{-1}) was obtained from purified rDNA (X/X females and X/Y*bb* males; because the X contains about 200 rRNA genes and the Y*bb* about 120, 83% of the rDNA of this stock is derived from the X). The purification of the rDNA using gradient centrifugation in the presence of mercury and actinomycin D will be published elsewhere. The X and Y chromosome rDNA was partially purified before digestion, electrophoresis and hybridisation. Each filter lane was cut in half lengthwise and the left half was hybridised with 28S RNA, the right half with 18S RNA. The length of different fragments is given in kb.
bb^{S1} bb^3 bb^4 bb^8

Fig. 3 *Eco*RI restriction pattern of rDNA from *bobbed* mutants. DNAs from females homozygous for bb^{S1}, bb^3, bb^4 and bb^8 mutations were extracted, treated with *Eco*RI and analysed by electrophoresis and hybridisation to ^{125}I-rRNA as described in Fig. 1.

Genetic mechanisms in the evolution of rDNA

The results of the experiments described here, and summarised in Fig. 4, have interesting implications for the mechanism of redundant gene evolution. If the X and Y *NO*s were to recombine with each other (and these would necessarily have to be double exchanges to maintain intact X and Y chromosomes; Fig. 4), and different repeat lengths are interspersed, then both *NO*s would be expected to display similar *Eco*RI fragment patterns. The fact that the 17-kb fragment is present on the X but absent from the Y chromosome supports earlier genetic evidence against recombination between X and Y rDNAs. It then becomes necessary to explain the fact that both the X and Y *NO*s contain apparently identical 18S and 28S RNA sequences[3], and share three of the four major discrete size classes of *Eco*RI fragments and at least one discrete fragment (2.8 kb) of the *Sma*I digest (Fig. 4). Unless genetic exchange between the X and Y *NO*s occurs on some occasions, we conclude that the similarities in the rDNA of these two *NO*s are maintained by selection pressure.

Drosophila is not unique in maintaining homologous genes on more than one chromosome. In humans, five chromosomes each contain a single NO[14,15]. In various organisms the same satellite DNA sequence is frequently found to cluster at the centric heterochromatic regions on several non-homologous chromosomes[16]. In *Xenopus*, the 5S RNA genes are located at the telomeres of at least 15 chromosomes[17]. These are but a few examples which illustrate the variety of homologous genetic sites that have been found to

be dispersed throughout the genome of a given species. In the case of the *Xenopus* 5S genes, it has been suggested that the relative homogeneity among the 15 gene clusters has been maintained by recombination[17,18].

In the examples cited above it has not been tested whether the homologous genes or satellites found on different chromosomes are truly identical or differ in some structural aspects. Furthermore, although there is some cytological evidence for recombination between some of these homologous regions on non-homologous chromosomes, as in the case of *Xenopus* 5S DNA[18], there is no direct genetic or physical evidence for such exchanges.

The situation with *Drosophila* rDNA poses a dilemma, in that two opposing interpretations of the available evidence may be proposed, both of which necessitate certain assumptions. The selection hypothesis is based on the prior genetic evidence against X–Y crossover events and places weight on the absence of 17-kb rDNA fragments on the Y *NO*. With these points in mind, we conclude that the X and Y *NO*s are indeed genetically isolated from each other. The apparent identity of the primary structure of the 18S and 28S rRNAs[3], and the similarity of the restriction fragment patterns which we observe would then be due to selection pressures. Although it is difficult to understand how selection would be sensitive to details of the spacer structure and to every nucleotide in the rRNA sequence, it must be remembered that the functional significance of spacer DNA and all of the structural gene information is still obscure. On the other hand, the recombination hypothesis asserts that genetic exchanges in the form of double crossing-over events do take place between the X and Y *NO*s. Such exchanges would not be detected by genetic experiments, and they would account for those similarities between the X and Y rDNAs which exist. This interpretation, however, necessitates the assumption that rDNA repeats of the 17-kb class

Fig. 4 A summary of the similarities and differences in the structure of X and Y rRNA genes. Since one-third of the X DNA resides in the heterochromatic block[13] (indicated as the darkened portion of the X) and since there are about 250 rRNA genes per X NO^2, this means that the X rDNA accounts for about 30% of DNA in the heterochromatin of this chromosome. Similarly, about 30% of the DNA in the short arm of the Y is rDNA. *Eco*RI and *Sma*I fragment sizes are given in kb. Infrequent *Eco*RI size classes such as those seen in Fig. 1b have not been included. Parentheses around certain size classes indicate they are minor components.

*Eco*RI	*Sma*I

(7.4)	2.8
(5.4)	2.3
either cannot participate in genetic exchange or are rapidly eliminated from the Y chromosome *NO*. This is a purely *ad hoc* assumption without any supporting experimental basis.

Our obsevations do not allow an unequivocal conclusion on the genetic and evolutionary mechanisms which determine the structure of *Drosophilia* rDNA, and which may operate in clusters of repetitive genes in general. Nevertheless, this work points up difficulties with the hypothesis that genetic exchanges are the main mechanism which assures the similarity of homologous regions on non-homologous chromosomes, and raises the possibility that selection pressures play a significant role in the parallel evolution of families of repetitive genes.

Significance of impulse activity in the transformation of skeletal muscle type

S. Salmons and F. A. Sréter

Department of Anatomy, Medical School, University of Birmingham, Birmingham B15 2TJ, UK, and Department of Muscle Research, Boston Biomedical Research Institute, 20 Staniford Street, Boston, Massachusetts 02114

The changes which follow cross reinnervation of mammalian fast and slow twitch muscles may reflect a capacity of skeletal muscle to respond adaptively to different functional requirements. This interpretation is supported by experiments in which long-term electrical stimulation was used both to reproduce and to oppose the effects of cross reinnervation.

IN adult mammals the motoneurones innervating slow twitch skeletal muscles generate a sustained low-frequency pattern of activity; in contrast, motoneurones supplying fast twitch muscles subject them to intermittent bursts of more intense activity[1]. The characteristic physiological and biochemical properties of the muscles emerge late in development, usually after birth, and in slow muscles this process seems to depend on the establishment of the adult pattern of motoneurone activity. If the motoneurones are rendered quiescent by isolation of the spinal cord a few days after birth, muscles which would normally have acquired slow contractile characteristics develop as fast muscles[2]. Even in the adult animal a fast muscle subjected to low frequency activity by an implanted stimulator[3] undergoes profound changes in all the properties which normally distinguish it from a slow muscle[4–8]. It has been pointed out[4,5] that this capacity for change would enable a muscle to accommodate the changing functional requirements which may be encountered during an animal's lifetime. According to this view, the late phase of differentiation of slow muscles in the neonate and the changes resulting from chronic stimulation of fast muscles in the adult both represent an adaptive response to continuous, low-frequency activation. The question then arises as to whether such a concept can provide insight into previous demonstrations of plasticity of skeletal muscle properties. The most important of these are the cross reinnervation experiments pioneered by Buller *et al.*[9].

In these experiments the motor nerves of a fast and a slow muscle were cut and cross anastomosed; as a result, the fast muscle was reinnervated by the nerve which previously supplied the slow muscle, and vice versa. The contractile characteristics then changed, the fast muscle becoming slower and the slow muscle faster. The authors considered, but were not convinced by, the possibility that these changes were due to changes in the patterns of impulse activity reaching the muscles. Instead they proposed that the contrasting properties of slow and fast muscles were

Fig. 1 Isometric twitch contractions of left and right EDL muscles (*a*) and right soleus muscle (*b*) recorded on identical time scales. The left EDL muscle (slower time course) has been stimulated at 10 Hz continuously for 20 weeks. Each time scale represents 100 ms with 1-ms divisions. Peak tensions are given in Table 1.
Fig. 2 Response of control soleus (*a*), stimulated EDL (*b*) and control EDL (*c*) muscles to a prolonged train of unfused tetani (25 Hz for 500 ms repeated every 1.25 s). The stimulated muscle is remarkably resistant to fatigue in these taxing conditions.

attributable to chemical trophic influences exerted by their respective motor nerves; cross union of the nerves caused the trophic substances to be carried to muscles of the opposite type, which were then transformed in accordance with the new innervation. Trophic concepts were not foreign to developmental biology, and the hypothesis was widely supported.

If cross union of the nerves interchanges the characteristic patterns of impulse activity reaching the slow and fast muscles, changes of the type observed would be in accordance with the adaptive-response hypothesis. The fast muscles, subjected to a continuous low frequency discharge, would tend to acquire slow muscle properties; the slow muscles, relieved of such a pattern of activation, would tend to undergo reciprocal changes. Although it remains to be confirmed that the firing pattern of a given moto-

neurone pool is fundamentally the same after cross reinnervation as before, Yellin[10] has reviewed indirect evidence which strongly supports this expectation.

Assuming, therefore, that there is a transposition of activity, can this alone account for the effects of cross reinnervation? This question has received balanced discussion (for example, refs 11 and 12) but has remained unanswered because of a lack of suitable data. We wish to report new evidence which makes it possible to compare, both qualitatively and quantitatively, the effects of cross reinnervation with those of a change in the pattern of impulse activity.

Long term stimulation

In their original work Salmons and Vrbová demonstrated marked slowing in response to long term stimulation in fast muscles of the rabbit and cat[5]. The results were confirmed and extended by two other groups, using different techniques of stimulation[13,14]. These experiments showed that the effects of stimulation were significant and were not confined to a particular muscle or species, but the duration of stimulation was not sufficient to afford a basis for comparison with cross reinnervation experiments. As a result of improvements in the design of the stimulator and in the surgical technique for its implantation, we have been able to stimulate fast muscles of the rabbit continuously for much longer periods than before. We present here the results of two experiments, each of 20 weeks' duration.

The animals were operated on in strictly aseptic conditions. In each case the stimulator capsule was implanted intraperitoneally, and the two flexible leads were passed subcutaneously to the left hind limb and fixed near the common peroneal nerve. The right limb served as an unoperated control. The animals were returned to the colony for the ensuing period, during which they remained in excellent condition and showed a normal gain in body weight. After 20 weeks a terminal procedure was carried out in which isometric twitch, tetanus and fatigue characteristics were determined for the tibialis anterior (TA), extensor digitorum longus (EDL) and soleus muscles of both hind limbs. Each muscle was set at the resting length at which it produced the maximum twitch contraction. Recordings from corresponding muscles of the two sides were made simultaneously in controlled thermal conditions. The muscles were then quickly excised, weighed, frozen in liquid nitrogen, sealed hermetically in polyethylene sachets and stored in solid CO_2 for biochemical analysis.

Figure 1 compares the twitch contraction of a stimulated EDL muscle with that of control EDL and soleus muscles of the contralateral limb. It is evident that the stimulated EDL muscle contracts even more slowly than a classical

	Control TA	Stimulated TA	Control soleus
Table 1 Effects of long term stimulation on a fast muscle			
Maximum twitch tension (g)	370	455	251
Time to peak twitch contraction (ms)	17.0	64.9	57.2
Time from peak to half-relaxation (ms)	17.9	77.1	91.1
Maximum tetanic tension P_0 (g)	3919	1829	1254

Maximum rate of rise of tetanic tension ($\%P_0$ ms^{-1})	3.06	1.11	1.73
Ca^{2+}-activated myosin ATPase activity (μmol mg^{-1} min^{-1})	0.66	0.18	0.22
Ca^{2+}-activated myosin ATPase activity after preincubation at pH 9.2 (μmol mg^{-1} min^{-1})	0.68	0.06	0.06
Ca^{2+} uptake by FSR ; initial rate (μmol mg^{-1} min^{-1})	2.19	0.21	0.56
Total uptake in 15 min (μmol mg^{-1})	3.81	0.55	1.52

Physiological and biochemical characteristics of the muscles whose twitch contractions are illustrated in Fig. 1. Fragmented sarcoplasmic reticulum (FSR) and myosin were prepared as reported earlier[20,21]. To determine the alkali lability myosin was preincubated at pH 9.2 in a solution containing 0.2 mg of protein per ml, 25 mM KCl, 10 mM Tris, 10 mM CaCl$_2$ for 10 min at 25 °C. At the end of this preincubation period the pH was readjusted to 7.6 by adding Tris to a final concentration of 50 mM and HCl as required. The ATPase reaction was then started by adding ATP.
Fig. 3 SDS–polyacrylamide gel electrophoretograms of myosin prepared from control TA muscle (*a*) TA muscle stimulated for 20 weeks (*b*), EDL muscle stimulated for 20 weeks (*c*), control soleus muscle (*d*). Myosin light chains characteristic of slow muscle are demonstrable after 4 weeks of stimulation[15]. Continued stimulation results in the successive disappearance of the fast muscle light chains, in the order LC_{2f}, LC_{3f}, LC_{1f} (refs 6 and 8).

qualitatively and quantitatively for the changes which result from cross reinnervation.

Equality of effect, however, does not necessarily imply equivalence of mechanism. It could be argued that changes in impulse activity and cross union of motor nerves achieve similar end results by different routes. To examine this possibility, we designed a null experiment in which the effects of long term stimulation would be set in opposition to those of cross reinnervation (for a preliminary account see ref. 17).

Stimulation versus cross reinnervation

In a group of 20 rabbits the common peroneal nerve and the motor nerve to the soleus muscle were exposed using a lateral approach (A. R. Luff, personal communication). One of the branches of the deep peroneal nerve supplying motor fibres to the fast muscles TA and EDL was carefully dissected free, cut and gently apposed to the peripheral cut end of the soleus nerve, using a single suture of 9/0 or 10/0 nylon. The reciprocal cross union was not performed, to provide conditions which favoured cross reinnervation of soleus but militated against self reinnervation by its original nerve. Since the bulk of the common peroneal nerve was left intact, the functional impairment incurred by this operation was minimal. Eight weeks after cross union, a stimulator was implanted in each of ten animals, subjecting the

slow muscle in the same animal. Similar results were obtained for the other stimulated fast muscles. In response to a prolonged train of 25-Hz tetani, the stimulated muscles proved to be even more resistant to fatigue than the solei, and showed, in the early phase of the fatigue record, the slight post-tetanic depression characteristic of slow muscles in place of the marked potentiation normally seen in fast muscles (Fig. 2). The biochemical results were no less striking, and showed a continuation of the trend described previously[6]. Table 1 illustrates typical data from one muscle pair. In addition to changes in these parameters, electrophoretograms of myosin light chains on sodium dodecyl sulphate (SDS)–polyacrylamide gels revealed that the light chains characteristic of fast muscles had been replaced entirely by light chains typical of slow muscles (Fig. 3). There was also evidence that the heavy chains of myosin had been replaced, since myosin from the stimulated muscle lacked the N-τ-methylhistidine amino acid residue characteristic of fast muscle heavy chains. Both these observations agreed with our earlier findings for shorter periods of stimulation[6,8,15,16].

These results represent a degree of transformation which matches or exceeds that of muscles cross reinnervated for much longer periods. We have shown, for example, that stimulation even for 12 weeks is enough to bring about the replacement of light and heavy chains of myosin noted above, yet both processes are still incomplete 1 yr after cross reinnervation[8,15]. The effects of a change in the pattern of impulse activity are therefore sufficient to account both

Fig. 4 Isometric twitch contractions of soleus muscles. In each case the left muscle of the pair has been reinnervated by the motor nerve from a fast muscle as a result of nerve cross union 16 weeks previously. In the upper picture the left muscle shows the increase in contractile speed which is the well documented consequence of cross reinnervation. The left muscle in the lower picture had been subjected to tonic stimulation through the new innervation for the previous 8 weeks; it exhibits a time course of contraction slightly more prolonged than that of the control muscle. Contractions of the left soleus muscles were elicited by stimulation of the left common peroneal nerve. In this and all other experiments of the series evidence for self reinnervation was sought by stimulating the left tibial nerve. The tension record then showed a small excursion of irregular shape and rapid time course (time to peak 20.07 ± 2.30 ms) which we attribute to residual mechanical cross-talk from the subjacent flexor hallucis longus muscle. In no instance was there any evidence of the slow twitch contraction which would have been indicative of self reinnervation.

Table 2 Characteristics of cross-reinnervated soleus muscles subjected to stimulation

	(a) Cross innervation alone		(b) Controls		(c) Cross innervation & stimulation
Time to peak twitch contraction (ms)	25.7 ± 0.7 $(n=6)$	$(P < 0.001)$	55.5 ± 2.9 $(n=16)$	$(P > 0.2)$	63.5 ± 8.3 $(n=6)$
Time to half-relaxation (ms)	26.7 ± 1.6 $(n=6)$	$(P < 0.001)$	74.2 ± 5.0 $(n=16)$	$(P > 0.9)$	72.9 ± 13.7 $(n=6)$
Twitch–tetanus ratio	0.15 ± 0.02 $(n=5)$	$(P < 0.01^*)$	0.21 ± 0.01 $(n=15)$	$(P > 0.2^*)$	0.16 ± 0.03 $(n=4)$
Max. rate of rise ($\%P_0 ms^{-1}$)	2.86 ± 0.17 $(n=5)$	$(P < 0.001)$	1.74 ± 0.14 $(n=13)$	$(P > 0.2)$	1.36 ± 0.21 $(n=4)$
Ca^{2+}–activated ATPase ($\mu mol\ mg^{-1}\ min^{-1}$)	0.48 ± 0.06 $(n=6)$	$(P < 0.001)$	0.26 ± 0.02 $(n=27)$	$(P > 0.6)$	0.28 ± 0.04 $(n=5)$
Alkali lability (% loss ATPase activity)	12.4 ± 6.3 $(n=6)$	$(P < 0.001)$	60.6 ± 2.8 $(n=15)$	$(P > 0.5)$	57.7 ± 2.6 $(n=5)$
Ca^{2+} uptake by FSR: initial rate ($\mu mol\ mg^{-1}\ min^{-1}$)	1.42 ± 0.24 $(n=6)$	$(P < 0.01)$	0.64 ± 0.11 $(n=17)$	$(P > 0.2)$	0.36 ± 0.09 $(n=5)$
total uptake ($\mu mol\ mg^{-1}$ per 15 min)	2.19 ± 0.10 $(n=6)$	$(P < 0.001)$	1.33 ± 0.09 $(n=17)$	$(P > 0.8)$	1.15 ± 0.31 $(n=5)$
ATPase ($\mu mol\ mg^{-1}\ min^{-1}$)	1.68 ± 0.29 $(n=6)$	$(P < 0.05)$	1.14 ± 0.12 $(n=17)$	$(P > 0.2)$	0.81 ± 0.17 $(n=5)$

*Paired *t* test.

Physiological and biochemical characteristics (mean±s.e.m.) are given for: *a*, soleus muscles cross reinnervated by a fast muscle nerve; *c*, muscles treated similarly but subjected to chronic stimulation during the last 8 weeks of the 16-week experimental period, and *b*, control soleus muscles. The data in columns (*a*) and (*c*) have been compared with control data in column (*b*) and *P* values for the differences assigned in each case. Except where noted, significance was assessed using Student's *t* test on the unpaired data. Additional control muscles have been included to establish reliable baselines and to provide more stringent conditions for the test of non-significance on the right hand side. In spite of the low mean value for the twitch–tetanus ratio in column (*c*), two of the animals in this group showed a higher twitch–tetanus ratio for the experimental muscle than for the contralateral control muscle. Of the muscles subjected to cross reinnervation alone (column (*a*)), none had a twitch–tetanus ratio greater than 60% of that of the contralateral control muscle.

cross reinnervated soleus muscle to a continuous train of impulses at 10 Hz delivered through the new innervation. These muscles would therefore have a pattern of activation substantially similar to that which preceded cross innervation. In the remaining animals dummy electrodes were implanted which were not connected to a stimulator. The rabbits were operated in matched pairs so that the two groups comprised animals with comparable histories. After a further 8 weeks the muscles were examined in a terminal procedure similar to that described above.

The adaptive response hypothesis required that the usual consequences of cross innervation be totally absent in the muscles which received stimulation. This expectation was indeed borne out. In Fig. 4 twitch contractions of soleus muscles from one pair of animals are compared. In the animal with dummy electrodes the cross innervated soleus muscle shows the usual substantial increase in the speed of contraction and relaxation. In the animal with a stimulator the cross innervated and stimulated soleus muscle contracts and relaxes even more slowly than its counterpart on the control side. Table 2 gives values for a broad range of physiological and biochemical variables measured in the two groups of animals. In each parameter the cross reinnervated soleus muscles differed significantly from the control muscles, whereas the muscles which were both cross reinnervated and stimulated did not differ significantly from the controls. Gel electrophoretograms of myosin light chains confirmed the presence, in cross reinnervated soleus muscles, of light chains characteristic of fast muscle, as reported previously[18]; on the other hand, cross reinnervated soleus muscles. Since it is highly unlikely that different chain patterns indistinguishable from those of control soleus muscles. Since it is highly unlikely that different mechanisms could produce such a detailed complementarity of effect we conclude that the effects of impulse activity and those of cross reinnervation are mediated in the same way.

A converse experiment would be to cross reinnervate a fast muscle with a nerve which previously supplied a slow muscle, and then relieved the muscle of the activity imposed by the new innervation. In fact this experiment formed part of the original study by Buller *et al.*[9]. No effects attributable to cross reinnervation could be discerned when steps had been taken to abolish normal motor activity by section of the spinal cord and lumbosacral dorsal roots. It was noted at the time that this observation could be interpreted within the framework of the trophic hypothesis if the synthesis, transport or release of trophic substances were dependent on the passage of nervous impulses. The finding is, however, equally well understood in terms of a more direct role of impulse activity, and as such is fully consistent with the other results presented here.

In summary, the data now available point to two general conclusions. (1) In the absence of an actual change in the pattern of impulse activity reaching a muscle, cross reinnervation has no significant effect. (2) A change in the pattern of impulse activity unaccompanied by a change in the motor innervation can produce effects equalling or surpassing those brought about by nerve cross union.

Implications for nature of neural influence

These observations rule out the possibility that the physiological and biochemical differences between fast and slow muscles are attributable to fundamental differences in the chemotrophic character of their motor nerves. Therefore in seeking an explanation of the neural influence on muscle differentiation we may confine our attention to impulse-dependent mechanisms. The data are not incompatible with the secretion of a trophic substance or substances by those α motoneurones, irrespective of type, which sustain a particular pattern of activity[19]. Such an hypothesis, however, now seems unnecessarily elaborate, for we have shown that the same phenomena can be explained just as adequately in terms of events taking place wholly within the muscle. According to this interpretation, gene expression in skeletal muscle is subject to the regulatory influence of one or more substances whose intracellular concentrations alter as a consequence of changes in the level of contractile or metabolic activity. Such a shift in emphasis from explicit chemical control by the central nervous

system to adaptive regulation by the muscle may prove to be a more fruitful concept in the design of future experiments in this area.

letters to nature

Spectral characteristics of transient X-ray sources

THE transient X-ray sources A1524−62 and A0535+26 were briefly observed by the University College, London, proportional counter spectrometer, experiment C on the Ariel V satellite (P. W. Sanford and J. C. Ives, unpublished). The resulting spectra help to complete the spectral history of these two sources, making seven sources for which there is now extensive spectral information. A general scheme emerges from these in which the sources with hard spectra ($n \lesssim 2$) show little spectral evolution and those with soft spectra ($n > 2$) exhibit marked softening with time. We discuss here this subdivision in relation to other properties of the sources.

The X-ray transient A1524−62 was first reported by Pounds[1] and a detailed light curve has been presented by Kaluzienski *et al.*[2]. These authors reported that the spectrum before peak intensity showed a slight softening, with the data at the precursor maximum being well fitted by a power law spectrum of photon index −2.5 and with no measurable soft X-ray absorption ($< 10^{22}$ atoms cm^{-2}, 1σ). Their data were not consistent with an isothermal Bremsstrahlung X-ray spectrum.

This source was observed by experiment C for two days, February 6–8, 1975, well after peak intensity, and the mean intensity in the 3–6-keV energy band was found to be 0.183 ± 0.001 photons cm^{-2} s^{-1} (1σ), in good agreement with Kaluzienski *et al.*[2]. The orbit-by-orbit intensities showed no variability

outside the 3σ uncertainties, setting an upper limit of 10% on intensity changes at the time scale of hours.

The spectrum obtained by integrating the data over this period is shown in Fig. 1 together with the best fitting power law spectrum. The best fitting parameters for both power law and exponential trial spectra are given in Table 1. The power law spectrum (index 4.23 ± 0.07) gives a better fit to the data,

Fig. 1 The spectrum obtained during the 2-d observation of A1524−62. The continuous curve is the best fitting power law spectrum whose parameters are listed in Table 1.
Table 1 Best fitting spectral parameters for A1524−62 and A0535+26

	Power law spectrum	Exponential spectrum
A1524−62 A0535+26	$dN/dE = AE^{-n}\exp(-N_H\sigma)$	$dN/dE = A\exp(-E/kT)$ $E^{-1}\exp(-N_H\sigma)$
A	30.6 ± 3.0	5.2 ± 0.5
n or kT	4.23 ± 0.07	1.43 ± 0.05
N_H	$(3.40 \pm 0.07) \times 10^{22}$	$(7.1 \pm 0.8) \times 10^{21}$
χ^2 for 8 d.f.	256	465
A	1.3 ± 0.08	Data not
n or kT	0.67 ± 0.03	consistent with
N_H	No detectable cutoff ($< 1 \times 10^{22}$)	single temperature fit
χ^2 for 29 d.f.	14	

σ is the Brown and Gould[3] absorption cross section.
The errors are 1 s.e., and are calculated by the least squares program used to fit the trial spectra.

Table 2 Summary of the characteristics of the seven most extensively observed transient X-ray sources

Source	τ_r (d)	τ_1 (d)	τ_2 (d)	Spectral parameters* Rise	Peak	Decay 1	Decay 2	I_{max} (erg cm^{-2} s^{-1})	D (kpc)	L_{max} (erg s^{-1})	Comments (OC= Optical candidate)

3U1543−47 refs 9, 10	4	10	100	n 3 (3.5 keV) N_H	4 $< 10^{22}$	4	4 (2 keV) 6×10^{21}	4×10^{-8}	3	4×10^{37}	OC = Variable (ΔM = 0.06) M giant
A1524−62 see text	4	30	60	n 1.5–2.5 N_H	$< 10^{22}$		4.2 3.4×10^{22}	5×10^{-9}			
A1118−61 refs 11–13	3	7		n 1.0† N_H 4×10^{22}	0.9† 4×10^{22}	1.1† 4×10^{22}		4×10^{-9}	3	4×10^{36}	Pulsating (P = 405 s). OC = Variable (ΔM = 0.1) Be Star
A1743−28 refs 14, 15		18	90	n N_H		3 10^{23}	3 10^{23}	3×10^{-8}	10‡	3×10^{38}	
A0535+26 refs 16, 17	6	20		n 0.67 N_H $< 10^{22}$	0.8 $< 10^{22}$	1.1 $< 10^{22}$		5×10^{-8}	1	5×10^{36}	Pulsating (P = 104 s). OC = Variable (ΔM = 0.7) Be Star
A0620−00 refs 18, 19	5			n 1.6 N_H $< 10^{22}$	5 5×10^{22}	5 (1.3 keV) 3.9×10^{21}		1×10^{-6}	2	4×10^{18}	OC = Blue star, varied by $\Delta M \simeq 8$ in coincidence with X-ray outburst

τ_r = Time for intensity to increase from $(I_{max}\,e^{-1})$ to I_{max}: τ_1 = time for intensity to decrease by a factor e after maximum intensity: τ_2 = sources Cen X-4, 3U1543−47, A1524−62, A1742−28 exhibited a second slower decay of e-folding time τ_2. Sources Cen X-4, 3U1543−47 showed a further rapid decay, after $(1–2) \times \tau_2$, leading to their disappearance: I_{max} = intensity at maximum; D = estimated distance; L_{max} = luminosity at maximum.
*For comparison, all spectra are described in terms of photon indices. Where not quoted directly, it has been roughly calculated from the reported temperature, which is also quoted in parentheses.
†Unpublished revised values of n and N_H, following calibration of Ariel V experiment C on the Crab Nebula.
‡Distances have been estimated from proposed optical identifications, except for A1742−28, the galactic centre nova, for which the 10 kpc is based on the celestial position and observed high column density[2].

but both spectra require significant soft X-ray absorption, equivalent, in the case of the power law fit, to a neutral hydrogen column of $(3.40 \pm 0.07) \times 10^{22}$ atoms cm^{-2}. The spectrum thus shows that a considerable spectral softening occurred in the source at or after maximum intensity.

The transient A0535+26 was observed by one or more of the Ariel V satellite experiments during the period April 13–June 6, 1975, and again between June 21 and August 15, 1975. The light curve (A. P. Willmore, unpublished) is fairly typical of other transient X-ray sources, with a precursor peak, a rise to maximum intensity (on May 1), followed by a quasi-exponential decay (time constant ~20 d). A subsidiary peak of 15% of the maximum has also been reported.

A0535+26 was observed by experiment C on April 28, that is, before maximum. The resultant data are shown in Fig. 2, together with the higher energy data from the crystal scintillator experiment on Ariel V (ref. 4). The experiment C data are best fitted by a power law spectrum with photon index of 0.67 ± 0.03, without measurable cutoff (see Table 1). However, neither a power law spectrum nor a single temperature exponential spectrum is consistent with the combined low and high energy data. Ricker et al.[5], from a balloon experiment on June 1, also found spectral steepening at higher energies not consistent with a single temperature exponential spectrum.

Comparison of the spectral data between 2 and 20 keV obtained by experiment C just before maximum, and by Ricketts et al.[6], suggests a slight spectral softening during the decay at these energies, but not so marked as for other X-ray transients.

The information on the most extensively observed transients is summarised in Table 2. A detailed review concerning the 5 most recent sources has been given by Willmore (unpublished). We stress that the values reported in Table 2 not directly given in the quoted literature, but estimated on the basis of the available information, are only indicative. This applies to the majority of the quoted time scales and to some of the spectral indices.

All the time scales are broadly similar, ranging from a few weeks to a few months, but this probably arises from observational selection effects. In fact there are indications of both faster[20] and slower[21] transients. Nonetheless, we are probably discussing a group of substantially similar events. Among the theories proposed for 'X-ray novae', variable accretion on to

compact objects in binary systems (refs 10, 15, 20, 22, 23, and F. K. Li, G. F. Sprott and G. W. Clark, unpublished) seems the most natural, in view of the similarities with known binary X-ray sources and the independent evidence of intermittent mass exchange in binary systems. The time scales should then be associated with the mechanism that drives the mass transfer.

Fig. 2 The spectrum of A0535+26. The experiment C data points for day 118, 1975 (1.5–15 keV) are combined with those reported by Coe *et al.*[4] (20–120 keV) for days 116–118, 1975.
It is apparent from Table 2 that, in their spectral characteristics, A1118−61 and A0535+26 are similar to each other and different from the other five sources. The first two have very hard spectra ($n \simeq 1$) which do not show strong variation with phase. The other five have spectral indices at, or after, maximum of $n \simeq 3$–5 and in four cases where spectral observations before maximum are available, there is evidence that the spectrum has varied, evolving from a hard to a soft state. In three cases the variation is from $n \simeq 1$ to $n \simeq 3$–5.

Moreover, the two hard sources exhibit regular pulsation and the proposed optical counterparts are Be Stars ($M \gtrsim 10\ M\odot$), while for the other five pulsation has not been observed and the available optical identifications (for 3U1543−47 (ref.24) and A0621−00 (ref. 25)) indicate low mass companions. (The absence of further possible identifications in this group is consistent with this.)

It has been pointed out (L. Maraschi, A. Treves and E. P. J. van den Heuvel, unpublished) that among all galactic X-ray sources there exists a strong correlation between the occurrence of pulsation, the hardness of the X-ray spectrum and the association with systems containing bright early type stars. The analogous grouping within the more limited sample of transients therefore acquires significance, and can be interpreted simply as reflecting the difference between the two classes of systems, of which Cen X-3 and Sco X-1 can be taken as prototypes. It is not clear why the spectral type of the primary star should be related to the properties of the X-ray emission from the compact companion and a possible model is discussed by Maraschi *et al*. The different spectral evolution of transients of the two groups is an important fact to be considered in models accounting for the different X-ray characteristics of the the two types of binaries.

The nature of association of equatorial spread *F* with magnetic activity

STATISTICAL studies based on a published data of f_0F_s have revealed that equatorial spread *F* depends inversely on magnetic activity during the sunspot maximum period but tends to disappear or even become positive in some seasons during the sunspot minimum period[1-3]. Somayajulu *et al*.[4], using a different technique, considered the occurrence of spread *F* during different phases of magnetic storms, and they concluded that the initial storm phase does not have any inhibiting effect on spread *F* occurrence and that spread *F* occurs in general during the main phase of the magnetic storms. They observed that, during the recovery phase when the field value is quite different from the normal value, there is no spread *F* but it is present when the magnetic field value is close to its normal value. To investigate this discrepancy with the earlier results further, the spread *F* behaviour has been studied[4] in relation to K_p indices, and for the Trivandrum data of 1970, and though the overall correlation between spread *F* and magnetic activity is negative, occurrence of spread *F* was found to decrease initially with increasing ΣK_p and then to start increasing at higher ΣK_p values. The effect of magnetic activity on equatorial spread *F* is reported here.

Equatorial spread *F* starts generally around 1900 LMT and lasts for a few hours. On some occasions, however, it persists throughout the night[5]. We have examined quarter hourly ionograms, during onset and development phases of spread *F*, from Trivandrum (dip−0.6°S) for 1970, and from Kodaikanal (dip−3.5°N) for 1969 and 1964, and the *f*-plots of Huancayo (dip−1°N) for 1968 to study the characteristics of spread *F* during its onset and development phase with magnetic activity as indicated by K_p indices. For this, the K_p indices for 1800–2100 LMT of Trivandrum and Kodaikanal and 1900–2200 LMT of Huancayo were used. The shift of 1h for Huancayo was used because K_p as given in the Solar Geophysical Data corresponds to that particular 3-h interval. The daily sum of K_p indices, represented by ΣK_p, was also calculated. The spread *F* data were grouped according to K_p and ΣK_p and percentage spread *F* was estimated for each (Figs 1–3).

In Figs 1–3, vertical bars indicate the 95% confidence limits. The yearly average sunspot numbers for the year 1968, 1969 and 1970 are 106, 106 and 105 respectively. These three years correspond to the period around sunspot maximum in that particular solar cycle and the year 1964 corresponds to the sunspot minimum (with a sunspot number of 10). In the following discussion no distinction is made between 1968, 1969 and 1970 in regard to the sunspot activity.

The most striking features of Figs 1, 2 and 3 is the reversal of the trend of variation of occurrence of spread *F* with increasing K_p value. This starts decreasing with increasing K_p but at a particular value of K_p it starts increasing again. It is

Fig. 1 Percentage occurrence of spread *F* at Trivandrum (75°E) against (*a*) the K_p index during 1800–2100 LMT (correlation coefficient = −0.19) and (*b*) against ΣK_p for the whole day (correlation coefficient = −0.29).
Fig. 2 Percentage occurrence of spread F at Huancayo (75°W) against (*a*) K_p index during 1900–2200 LMT (correlation coefficient $= -0.12$) and (*b*) ΣK_p during the whole day (correlation coefficient $= -0.1$).

even greater at the highest K_p value compared to that at the quietest condition ($K_p = 0$), as can be seen clearly from Figs 2 and 3. In Fig. 1 the two are almost equal. The value of K_p at which the reversal occurs at Huancayo is less than that at Trivandrum and Kodaikanal. Another important feature is that the decrease in spread F with K_p is rather slow initially at Trivandrum and Kodaikanal compared to that at Huancayo but later the opposite is true. For 1964 the general level of spread F is low at Kodaikanal as can be seen from Fig. 3. The reversal of the trend is seen as for the sunspot maximum year but with a major difference: it occurs at a much lower value of K_p($= 1$). The correlation coefficients between spread F and K_p index are also shown in Figs 1, 2 and 3. They are all negative except for 1964 at Kodaikanal. The coefficients are all $> 95\%$ confidence limit. This shows that though the relationship between K_p and spread F reverses at high K_p, the overall correlation between the two remains negative in accord with the earlier results[1-3]. The overall negative correlation obviously arises because days with high K_p value (or ΣK_p) are less numerous than those with low K_p value (or ΣK_p).

It is known that the onset of spread F is earlier in the period of sunspot maximum compared with its onset in sunspot minimum period. We have here considered the same 3-h

Fig. 3 Percentage occurrence of spread F at Kodaikanal (75°E) against the K_p index during 1800–2100 LMT. ○, Data for 1969, correlation coefficient $= -0.09$; □, data for 1964, correlation coefficient $= +0.12$.
period (1800–2100 LMT) both for sunspot maximum and minimum years for Kodaikanal As such, the occurrence of spread F during the onset and development phase of spread F in the sunspot minimum period may be underestimated. Its variation with K_p may not, however, be affected.

The reversal at a lower K_p value for Huancayo during the sunspot maximum years is quite likely to be true for the sunspot minimum period also. One would then expect that the occurrence of spread F starts increasing right from $K_p = 0$. This may result in comparatively more spread F at Huancayo during sunspot minimum relative to that at sunspot maximum because there would be more days with low K_p than with high. In fact many investigators[3] reported just this.

v.l.f. emission from ring-current electrons

v.l.f. emissions associated with the enhancement of ring-current electrons during magnetic storms and substorms have been detected by the satellite S^3-A (Explorer 45) on an equatorial orbit[1,2]. The emissions observed near the geomagnetic equator consist of essentially two frequency regimes; one above the electron gyrofrequency at the equator, f_H—the electrostatic mode[3-5], which peak near $(n+\frac{1}{2})f_H$, where n is positive integer (emissions up to $n = 10$ have been observed[3])—and the other below f_H—the whistler mode, which has a conspicuous gap at exactly $f_H/2$. Here we describe the characteristics of this v.l.f. emission and the associated enhancements in electron intensity as well as the anisotropies of the ring-current electron distribution, and we also give an interpretation of the bimodal frequency distribution of the equatorial whistler mode emissions. This distribution has been known for the past few years but has not been well explained[6,7].

Figure 1 is a part of the wide-band data obtained during the main phase of the December 17, 1971 magnetic storm[1]. Figure 1*a* is the a.c. magnetic field data measured by the search-coil magnetometer with the upper cutoff near 3 kHz (ref. 8) and Fig. 1*b* is the a.c. electric field data obtained by the electric field sensor with the upper cutoff of 10 kHz (ref. 9). The figure (*a* and *b*) shows the time sequence of the observed emissions along the inbound orbit (No.101) of the satellite as f_H changes from ~ 3.0 kHz at 2000 UT to 6.0 kHz at 2100 UT. Although the automatic gain control of the sensor produces occasional spurious intensity variations, it should be noticed that emissions at frequencies $> f_H/2$ are generally stronger and more continuous than those $< f_H/2$.

Another example of the equatorial magnetospheric v.l.f. emissions is shown in Fig. 2, where the emission data, which were observed during the substorm on January 22, 1972, are digitised in 1-min bins and are normalised by the value of f_H computed from onboard magnetometer data. Shown in the upper portion of Fig. 2 is the magnetic latitude of the satellite at the time of the observations. The dark and light shades correspond to the electrostatic mode and the whistler mode emissions, respectively. The frequency of occurrence graph, on the right, shows that the whistler mode has a bimodal frequency distribution with a sharp dip at exactly $f_H/2$.

The variations of the differential electron intensities ($cm^{-2} s^{-1} sr^{-1} keV^{-1}$) for the same date are shown in Fig. 3 for electrons of 90° pitch angle and for electrons with the smallest observable pitch angle (close to 25°). The difference between these two plots for each energy is a manifestation of the pitch-angle anisotropy and is indicated by the vertical hatched lines.

MLT $= 22.6$
Fig. 1 A part of the v.l.f. emission event during the main phase of the geomagnetic storm on December 17, 1971. The emission of an a.c. magnetic field ($f \leqslant 3$ kHz) and an a.c. electric field ($f \leqslant 10$ kHz), are indicated in (*a*) and (*b*) respectively. The numbers shown at the bottom are: (1) the universal time, UT; (2) a measure of geocentric distance of the satellite in the equatorial plane, L (in R_E units); (3) the magnetic latitude, M Lat; (4) the magnetic local time, MLT. The electron gyrofrequency, f_H, changes from 3,067 kHz at 2000 UT to 3,662 kHz at 2030 UT and to 5,986 at 2100 UT.
Fig. 2 The frequency distribution of the v.l.f. emissions observed by the S³-A satellite during the substorm on January 22, 1972. The frequency distributions made by accumulating the number of occurrence in each frequency interval ($\Delta f/f_H = 0.01$ is used) are shown on the right side of the figure. There is a conspicuous dip in the bimodal frequency distribution of the whistler-mode emission at exactly $f_H/2$.

The times indicated by horizontal hatched lines and grey shade are the periods when the emissions shown in Fig. 2 were observed and when the satellite is inside the plasmasphere, respectively. A short period around 0700 UT (approximately 2000 MLT—inside the plasmasphere) represents the double structure of the evening side plasmapause[2].

We can see that the v.l.f. emissions are observed only when the satellite is outside the plasmasphere and that the beginning of the emission coincides with the satellite's encounter with the large electron fluxes there. It should be noticed, however, that the increase in the electron intensities associated with this observed v.l.f. emission is limited to the low energy electrons only (< 6 keV for this event).

To see the energy spectrum of electrons, the flux spectrum at 0730 UT on January 22, 1972 is plotted in Fig. 4. The mean quiet period spectrum observed by this satellite, which has been given by Lyons and Williams[10] is also plotted for comparison. Approximating these energy spectra and the pitch angle distribution of electrons by

$$j(E, \alpha) \sim E^{-n} \sin^m \alpha \qquad (1)$$

The parameters n and m for three energy regimes are also shown in Fig. 4. We can see that not only the intensity increase but also the anisotrophy is larger in the lower energy electrons.

The growth rate of waves excited by resonant electrons increases with increasing anisotropy of the electrons, and the peak of emission shift to higher frequency as the anisotropy of the resonant electrons increases, particularly for the soft spectrum electrons. For electrons obeying equation (1), the peak of emission is $> f_H/2$ for $m \gtrsim 2$ with $n \gtrsim 1$ (ref. 11). The emission above $f_H/2$ can be also excited by the cyclotron instability of a plasma composed of thermal and quasithermal (20–50 eV) particles if the anisotropy of the quasithermal plasma is suitably large[12]. The S³-A satellite did not, however, carry detectors for these low energy plasma particles.

Since the resonance energy, E_R, for electrons encountering the

whistler waves of frequency, f, is given by

$$E_R = E_B \frac{f_H}{f}\left(1 - \frac{f}{f_H}\right)^3 \qquad (2)$$

where

$$E_B = \frac{B^2}{8\pi N} \quad \text{or} \quad E_B = 250\left(\frac{f_H}{f_p}\right)^2 \text{ (keV)} \qquad (3)$$

B, N and f_p are the magnetic field intensity, plasma density (cm^{-3}) and plasma frequency (kHz), respectively, the energies of electrons resonating with the whistler waves of frequency $f > f_H/2$ are always smaller than those for $f < f_H/2$. In this sense, the large electron intensities shown in Figs 3 and 4 are able to excite only the emissions of higher frequencies, $f \gtrsim f_H/2$.

Fig. 3 Variations of the directional differential electron intensities (cm^{-2} s^{-1} sr^{-1} keV^{-1}) on January 22, 1972. The two lines for each energy correspond to the intensities at pitch angle 90° ($\times$) and of the smallest observed pitch angle (close to 25°) (●).
Fig. 4 Differential energy spectra of the enhanced ring current electrons during the v.l.f. emission event compared with the mean quiet time spectrum (■)[10]. The shaded part between two directional intensities ($\times$ for 90°, ○ for 25°) shows the anisotropy of the increased electron intensities at different energies. The parameters n and m for three energy regimes are also indicated in the respective parts of the curves.

On the other hand, because of the ~11° tilt of the Earth's magnetic dipole axis from the rotation axis and the small inclination (~4°) of the S³-A satellite orbit, emission events are occasionally observed off the equator. Figure 5 shows one example which was observed during the substorm on January 18, 1972. The notation is the same as in Fig. 2, and as indicated by the line in the upper left, the magnetic latitude of the satellite during the event was >10°.

From this figure, we can see that the frequency distribution >$f_H/2$ differs significantly from those of the near equatorial events, indicating that the off-equator propagation of this >$f_H/2$ magnetospheric emission is non-ducted. On the other hand, the emission <$f_H/2$ is similar to that observed near the equator. It seems therefore that these waves are duct-propagated with an upper cutoff of $f_H/2$, which was known from the investigation of whistler propagation in both ground and satellite observations[13-15].

Based on the information described above, the formation of the bimodal frequency distribution of the equatorial whistler mode emissions with a sharp dip at $f_H/2$ can be explained as follows: (1) The emission >$f_H/2$ is produced near the equator by
Fig. 5 The normalised frequency distribution. In this off-equatorial emission event, the emissions $> f_H/2$ are weaker than the emissions $< f_H/2$ and the frequencies are quite different from the near equatorial results shown in Figs 1 and 2.

the enhanced ring-current electrons, resonating with the weak broad band whistler-mode noises which are found quite generally in the region of $3 \lesssim L \lesssim 10$ of the Earth's magnetosphere; (2) the emissions $< f_H/2$ are produced in a similar manner near the equator but slightly outside the observing location, where the magnetic field is weaker, the corresponding gyrofrequency, f_H', is significantly smaller than that at the observing location, f_H; (3) those locally produced emissions with $f > f_H'/2$ propagate unducted off the equator in the magnetosphere, and are reflected back towards the equator from the regions where the lower hybrid resonance frequency, f_{LHR}, exceeds the frequencies of

these waves[16], as depicted schematically in Fig. 6; (4) the reflected waves propagate toward the equator in the narrow density-enhanced ducts whose upper cutoff is $f_H/2$ (refs 13–15).

Since $f_H' < f_H$, we can find, for example, that the emission produced at a frequency $f \simeq 0.55 f_H'$ (that is, $f > f_H'/2$) arrives at the observing location with $f = 0.45 f_H$ (that is, $f < f_H/2$), as indicated in Fig. 6.

This idea for the formation of the bimodal frequency distribution with a dip at $f_H/2$ (which is also called "the band of missing emissions" in geomagnetic equatorial whistler emissions, such as chorus[1,2,6]) has other support. Data gathered by the OGO-3 satellite when crossing the geomagnetic equator on January 21, 1967 (ref. 17), are shown in Fig. 7. The magnetic latitudes corresponding to Fig. 7a, b, c are $\sim 0°$, $-2°$ and $-5°$, and the arrow on the left side of each indicates the frequency corresponding to $f_H/2$. From these figures, we can see that: (1) emission at $f > f_H/2$ is stronger and more continuous than at $f < f_H/2$, indicating that the emission at $f > f_H/2$ is observed rather close to its source; (2) emission at $f < f_H/2$ is striated, indicating that this emission propagates in narrow ducts of enhanced ionisation; (3) there is no coherence between the upper and lower frequencies, except for the bottom example, (which is rather non-equatorial), indicating that the sources of those two are different, or at least separated.

Further aspects of our theory, including the growth rate of the emissions based on the observed large low energy electron intensity and anisotropy, and the ray tracing of non-ducting emissions produced near the equator with frequencies $f > f_H/2$, are being studied. Finally, there remain effects which are not well understood in the formation of the missing emission band carried by the interference of two modes of propagation and by the Landau damping for a frequency $\sim f \lesssim f_H/2$ (refs 6, 11 and 17). Investigations on the relation between the whistler-mode emission and the electrostatic-mode emission might produce more information about these problems.

Gas movement through sea ice

UNLIKE ices from pure or freshwater, sea ice is a highly permeable medium for gases. We have found that: (1) the migration of these gases along the grain boundaries (probably in brine channels) was 2 to 6 times as great as that at right angles to the principal axis of the grain boundaries; (2) the rate of penetration is ~ 30 cm h⁻¹ at −15 °C for halogenated gases (in nl ml⁻¹ quantities) and 60 cm h⁻¹ at −7 °C for carbon dioxide (in μl ml⁻¹ quantities); (3) the vertical migration is about twice as fast as horizontal migration at −15 °C, and (4) for one experiment with a block of semi-fresh pressure ridge ice, the migration rate was ~ 60 cm h⁻¹ at −15 °C. The permeation constants are estimated to be 10^{-7} cm² s⁻¹ atm⁻¹ at −15 °C for SF_6, and 2×10^{-5} cm² s⁻¹ atm⁻¹ for CO_2 at −7 °C. These data strongly indicate that gas migration through sea ice is an important factor in ocean–atmosphere winter communication particularly when the surface temperature is > −10 °C.

It has been correctly reported[1] that pure water and lake water ice are effective barriers against any significant migration of gases at temperatures < −0.5 °C. Their permeabilities are 10^6 less than that of carbon dioxide through water, with lake water ice an order of magnitude more permeable because of traces of impurities in the ice. This is understandable when one considers results[2,3], which show that the size of veins at three grain intersections open or close drastically within a few hundredths to a few tenths of a degree below the freezing point for freshwater ices.

On the other hand, large brine loads would extend the temperature range over which these vein and brine channels would remain open to several degrees below the freezing point. The sea-ice temperature, of course, will be a gradient from −2 °C at the water–ice interface to that of the prevailing atmosphere at the air–ice interface.

We also observed brine to enter bore holes in noticeable quantities after 12 h at −15 °C: at −10 °C it was only slightly faster. At −6.5 °C brine temperatures, however, bore holes filled to the hydrostatic level within an hour. The bore holes were 50–75 cm deep in 2-m thick ice. Ink in brine was observed to travel 30 cm vertically within 30 min through a freshly quarried block of sea ice at −7 °C. There are also results[4,5] on the flow of water through ice at temperatures close to 0 °C.

Tracer gases (sulphur hexafluoride, perfluoromethyl bromide, and perfluoroethyl bromide) were resolved and detected in an electron capture gas chromatograph with a short Porpak N column. Carbon dioxide was analysed with a thermal conductivity device. Experiments with shorefast annual ice using halogenated tracer gases were carried out in April at the Naval Arctic Research Laboratory (NARL) at Barrow, Alaska, and other *in situ* experiments in pack ice were performed at the Arctic Ice Dynamic Joint Experiment (AIDJEX) Camp Caribou located ~240 miles NE of Barrow. Both sets of experiments provided the same rate values at −15 °C. Another set of *in situ* experiments at NARL in May, when the temperature was −7 °C, provided the data for CO_2. In early experiments, bore holes were charged with one or more of the halogenated tracer gases, and then the top of the hole was covered with a metal plate which was sealed to the surface with fresh water and snow. At intervals, cores were taken beside the sealed holes, leaving 25–30-cm ice walls. The cores were taken in the plane of the predominant ice grain boundaries from the gas-spiked holes, and perpendicular to it. These cores were immediately placed in gas-tight containers made from glass sewer pipe, and then flushed with He by means of stopcock fittings on the ends of the containers. In the laboratory, large loads of tracer gases were found in the head space gas from cores taken ~1.5 h after the start of the experiments. For all other experiments, 5-cm diameter bore holes were drilled to a depth of up to 1 m in the ice outside the work hut. Ice walls of 30–90 cm were left between three vertical holes. Metal plates with swagelock fittings were sealed to the ice over these holes with snow and freshwater. The two outside holes were manifolded through a closed

loop pump and switching system so that samples could be valved directly into the gas chromatograph. In other experiments, diagonal holes were bored in the ice so that 10- and 20-cm ice walls had to be penetrated vertically by the gases.

This work was supported by a grant from the Office of Naval Research.

On the marine geochemistry of cadmium

STUDIES of the geochemistry of trace metals in sea water are of great potential importance, given the wide diversity in their properties. Knowledge of their distribution provides information not only about the specific chemical processes in which they are involved but also about the formation, destruction and diagenesis of the major solid phases in which they become incorporated by biological and authigenic processes. Previous efforts to elucidate the behaviour of cadmium in the ocean have produced no systematic correlations with other oceanographic properties[1]. At the low levels encountered (< 0.1 parts per 10^9), problems with analysis and with contamination during sampling can be severe. Recent advances in analytical and handling techniques have led to progress in our understanding of other trace metals[2-4], hence a re-examination of the marine geochemistry of cadmium is now appropriate. This note describes the general distribution of cadmium in the ocean, based on three detailed vertical profiles from the Pacific.

Fig. 1 Cadmium, phosphate, and silicate profiles for three stations in the Pacific Ocean. ○, Silicate; ●, phosphate for (*a*) Stn 219 (*b*) Stn 226 and (*c*) Stn (293).
Fig. 2 Cadmium concentration against phosphate for three Pacific profiles (●, Stn 293; ✳, Stn 219; ■, Stn 226) and three data points from the literature, B (ref. 4) and K (ref. 6).

Station locations were chosen to cover a broad range of oceanographic conditions, from the south-western Pacific, S of New Zealand (Stn 293) to the temperate mid-Pacific, E of Japan (Stn 226) and the North Pacific upwelling region in the Bering Sea (Stn 219) (Table 1). The samples were taken using rosette-mounted 30-l PVC Niskin bottles with epoxy-coated internal springs and stored in acid-leached polyethylene containers, after acidification to $pH = 2$. The handling of containers and samples is described in detail elsewhere[3]. Cadmium was preconcentrated from 100-g samples by cobalt pyrrolidine dithiocarbamate coprecipitation[5] and analysed by atomic absorption spectrometry using a heated graphite atomiser (E. A. Boyle and J. M. Edmond, unpublished). The estimated precision and accuracy of the analysis is ± 0.1 nmol kg^{-1}. The cadmium data and relevant hydrographic information are listed in Table 1.

Depth profiles of cadmium are shown in Fig. 1 along with profiles of the nutrients phosphate and silicate. It is readily apparent that cadmium is depleted in the surface ocean relative to the deeper waters. Such a distribution indicates uptake by organisms at the surface and regeneration from sinking biological debris deeper in the water column. The range in concentration is over a factor of at least ten, from 0.1 ± 0.1 to 1.1 ± 0.1 nmol kg^{-1}.

The cadmium profiles resemble those of phosphate more than silicate: the concentrations increase rapidly with depth to a maximum at ∼ 1 km and then decrease slightly below this. The covariance with phosphate is consistent for all stations (Fig. 2) and suggests that cadmium is regenerated in a shallow cycle, like the labile nutrients, rather than deeper in the ocean, as is silicate.

The results are compatible with some recent cadmium data. Bender and Gagner[4] report values for the Sargasso Sea; surface (0.05 nmol kg^{-1}) and deep (0.30 nmol kg^{-1}): Knauer and Martin[6] give a value for the 1,000-m depth near Hawaii (1 nmol kg^{-1}) and report surface concentrations below their detection limit (0.2 nmol kg^{-1}). Estimates of the phosphate concentrations at these locations were made using data from nearby GEOSECS stations, and are plotted in Fig. 2. The agreement is excellent. The cadmium–phosphate correlation observed in these stations probably holds throughout the world ocean.

A detailed comparison of the chemical composition of plankton with the hydrographic correlation of cadmium and phosphate is not possible because few analyses include both elements. Goldberg *et al.*[7] report analyses of *Sargassum* and planktonic animals with Cd/P molar ratios of 4×10^{-4} and 6.5×10^{-4} respectively. These values are close to the water column ratio 3.5×10^{-4}. Martin and Broenkow[8] observed

cadmium enrichments by a factor of 3 in plankton from the Baja California upwelling region relative to organisms in the open Pacific. Cadmium, like phosphate, is enriched in the surface waters of upwelling regions (for example, Stn 219) relative to areas of lower productivity. The phosphate content of the Baja California waters is about a factor of 3 higher than further away from the coast (R. C. Dugdale and M. L. Healy, unpublished; F. R. Richards, unpublished), and a similar enrichment factor should apply to the cadmium concentration in these waters. It is evident that the cadmium content of plankton depends on the concentration in the water in which the organisms grow. A mechanistic interpretation of the cadmium–phosphate correlation requires information on the site of incorporation of cadmium in organisms and sinking biogenic debris. Similar depth profiles would result if cadmium were carried in either the soft tissues of organisms or in the more

rapidly dissolving hard parts, such as celestite ($SrSO_4$) (ref. 9). Future work on the chemical composition of marine plankton should attempt to establish the location of the various elements in the organisms.

There is little information on the cadmium content of river waters. Where measurements have been attempted, concentrations were often near or below the detection limits of the instrumentation (ref. 10 and refs therein). To derive an estimate for the continental supply rate of this element, a glass fibre-filtered sample from the mouth of the Amazon River was obtained at Macapa, Brazil in May 1974. The cadmium concentration of this sample (0.6 nmol kg^{-1}) may be tentatively taken as representative of world rivers. The resulting estimate of the oceanic 'residence time' of cadmium is ~ 50,000 yr.

Last, it should be noted that there is no evidence in these data for cadmium pollution in the open ocean. Indeed, the

efficient scavenging of this metal by organisms will rapidly remove pollutant cadmium from the mixed layer so that it should not be expected to accumulate in the surface ocean.

Combustion sources of atmospheric chlorine

Estimates of the primary sources of tropospheric gaseous chlorine compounds (ClX) which have the potential for reaching the stratosphere, list man-made halogenated hydrocarbons (such as refrigerants and aerosol propellants), man-made and natural hydrogen chloride sources (such as burning of waste materials and volcanic activity), sea spray and naturally occurring chlorinated hydrocarbons. The existence of an unidentified source of tropospheric ClX has been proposed[1-4] which has since been postulated to be combustion. The purpose of this paper is to examine and estimate the strength of fires as ClX sources.

Chlorine, as well as the other halogens, serve as free-radical traps in flames and are effective in suppressing flaming combustion and promoting glowing combustion[5]. When chlorine compounds are heated in contact with cellulose materials, ClX is produced either by reactions involving the hydroxyl groups of the cellulose, or by reactions involving 'active' water formed *in situ* by dehydration[6]. About 1% of the combustion products evolved from wood is methane[7], which can be converted to methyl chloride by the chlorine available in the wood. Bethge and Troeng[8] found that the natural chlorine content of wood pulp and other cellulosic materials ranged from 0.07 to 2.68 mg g^{-1}, that the chlorine content of wood was greater by an unspecified amount than that of unbleached wood pulp, and that 86% of the chlorine content of the sample was lost during combustion.

Lovelock (personal communication) refined his earlier estimate[1] to 1 cm^3 of methyl chloride gas produced for each gram of cellulose burned in glowing combustion. This is approximately equivalent to 2.2 mg of methyl chloride or 1.6 mg Cl produced per gram of cellulose burned. If the 86% loss of Cl during burning is representative, the average initial chlorine level in cellulose is 1.8 mg g^{-1}. There is good agreement between experiments, excepting those which involved flaming combustion.

The common combustion products of most burning plastics are smoke, CO, CO_2 and H_2O vapour. Trace amounts of extremely complex liquid, solid and gaseous combustion products also occur[9]. PVC is different from other plastics because its principal combustion product is HCl (refs 10, 11). The overall chlorine content of PVC is ~ 49%, varying with the amount of various pigments and lubricating organic additives. Yields of HCl during thermal decomposition vary from almost complete (583 of a possible 584 mg (ref. 12)) to ~ 95% (ref. 10).

PVC is widely used for many purposes and consequently is usually involved to some extent in any man-made fire. The most reliable estimates of PVC production in the USA are given in Table 1. In 1974, 6.5% of this production went into various forms of packaging materials[13], which are ultimately disposed of as waste. As a result of Executive Order 507, much of the municipal waste and waste from suburban and rural areas in the USA is now buried. Some of the PVC is burnt in free-burning fires such as those in fireplaces and home incinerators. Much of the HCl produced in these fires does not reach the atmosphere because it is quickly deposited on adjacent surfaces, is mixed with smoke particles (both solid and liquid) and is absorbed by the water produced during combustion. An indication of the reactivity of HCl and its presence in smoke from the burning of waste is the heavy corrosion of the metal parts of municipal incinerators and the observed inhibition of combustion of municipal wastes[14]. I estimate that ~ 50% of the packaging material was burnt in 1965, decreasing linearly to 10% in 1974, and that 10% of the evolved Cl is converted to methyl chloride and other chlorinated hydrocarbons. Table 1 shows that the production of methyl chloride from waste has only recently declined.

Disposition of the rest of the PVC in the USA apparently is not available. English estimates[15] are that 50% of the PVC produced goes into construction. The National Fire Protection Association estimate of the loss rate of new construction because of fire is $0.59 per $100 or ~ 0.6% yr^{-1} (ref. 16). Thus, ~ 0.3% of the PVC produced yr^{-1} is burnt in urban and industrial fires and ~ 10% of this amount is converted to chlorinated hydrocarbons. As shown in Table 1, the total man-made production of methyl chloride is continuing to rise, in spite of the reduction in the burning of waste.

The area burnt in wildfires is well documented[17]. In 1974, 537,020 ha were burnt in the small wildfires. The amount of fuel per unit area (fuel loadings) was quite variable ranging from 1 to 2,500 t ha^{-1}. Estimates derived from wildfire data (O. L. Holmes, US Forest Service, R-5, personal communication) and other sources[16-21] indicate that the average fuel loading is ~ 30 t ha^{-1}. Of this ,~ 40% is fast burning fine material; the residual is coarse material which tends to burn by glowing combustion.

Controlled burning encompasses a large range of activities including forest residue reduction, agricultural waste burning and other mild fires. The weather and fuel conditions for these fires are deliberately chosen to promote low flames and glowing combustion to minimise fire intensity, and to reduce the probability of fire escape. Much of the agricultural residual materials have a high mineral content (for example, rice straw 15%, sugar cane 30%) which also promotes glowing combustion and increases the production of methyl chloride.

Yamate's[22] survey of the burning of forest and agricultural residues in the United States is in agreement with other sources[19-21] except for forest residue reduction in the Pacific North-western States which is 424 times greater. The Forest Service was taken as the authoritative source. All values in Table 2 of the amount of fuel burnt in forests have been decreased by 40% to account for the rapid burning of fine fuels.

It is generally accepted by observers of large fires that the convection columns reach altitudes of 10 km or more[23]. Cramer of the US Forest Service (personal communication) measured the tops of the 1933 and 1939 Tillamook, Oregon, fires at 12 and 13 km. The convection column above the 1967 Sundance Fire in Montana reached 10.5 km and was carried to 13 and 14 km by the isentropic flow field downwind[21].

Table 2 Methyl chloride from combustion sources in the USA, 1972–74

Source	Area burnt (ha)	Fuel loading (t ha^{-1})	Fuel burnt (t yr^{-1})	Methyl chloride (t yr^{-1})	Totals (t yr^{-1})
Agricultural					
Field residues	1,767,771	1.13	2.00×10^6	2,700	2,700
Forests					
Forest residues					
Pacific North-west	Not currently available		39.4×10^6	52,000	
California	Not currently available		0.9×10^6	1,200	
Southern States	8.10×10^5	25	20.0×10^6	26,700	
Rest of USA	8.50×10^5	3	2.5×10^6	3,300	83,200
Wildfires (A, B, C, D, E)	4.69×10^5	30	14.1×10^6	18,600	
Wildfires (F, G)	2.29×10^5	30	18.9×10^6	24,900	43,500
Man-made (Table 1)					80,600
Totals					210,000

These large fires may spread at rates up to several thousand ha h^{-1}. Fuel loadings vary from one to as much as 1,250 t ha^{-1}. Combining the fire spread rates with the heat of combustion of wood (~ 5,000 calorie g^{-1}) gives an energy release rate of 10^9–10^{11} calorie s^{-1}. Such energy release rates are as great as the largest natural thunderstorms[24]. The primary energy source is locally intensive at the ground rather than in the extensive of the cloud as in a thunderstorm. Studies of convection columns[22] show that most of the air passes through or near the bottom of the column in or near the combustion zone. There is a little evidence of lateral entrainment into these convection columns at heights > 100 m above the fire. Condensation within the convection column is apparently determined by the lifting condensation level of the ambient air at the ground level. This type of fire usually occurs in extremely dry conditions and, if condensation occurs at all, the level is > 6,000 m.

Analysis of the Project Flambeau convection column[23] showed that these large fires followed a consistent pattern, and that a fire had to have at least 27 ± 2 hectares burning (not burnt) to be classified as a mass fire. The application of the Project Flambeau results to large wildfires requires an analysis of the geometry of these fires. In large, vigorously spreading wildfires the flame front at the fire's head is ~ 150 m thick in timber and 50 m thick in brush. The shape of the burnt area is a complex function of terrain, wind, humidity, fuel moisture, fuel distribution, percentages of live and dead materials and other factors. A variety of simple models can be assumed, but the simplest is a square, of side 2r, with two semicircles of radius r at each end. The active fire front is of radius r and of thickness d which approximates the final form of the Sundance fire[17].

The total area burnt A_B is the sum of the end semicircles and the centre square

$$A_B = \pi r^2 + 4r^2 \qquad (1)$$

The significant burning area, A_s, is

$$A_s = \pi (2rd + d^2)/2 \qquad (2)$$

Solving equation (2) for r and substituting into equation (1) gives the area burnt during a mass fire as

$$A_B = (\pi + 4)[(A_s/d) + (d/2)]^2 \qquad (3)$$

Substituting the characteristic values for d gives minimum sizes of $A_B = 4.09 \times 10^6$ m^2 for timber and $A_B = 4.16 \times 10^7$ m^2 for brush.

Fires this size are categorised as class F (1,000 to 4,999 acres) and class G ($\geqslant$ 5,000 acres) in the USA where there were 227 class F and 53 class G wildfires in 1974 (ref. 17). These fires burnt a total of 628,605 ha (1,552,654 acres), which is a normal yearly area. The flame front primarily burns the fine fuels which average 12 t ha^{-1}. About 50% of the remaining fuel, or 8 t ha^{-1}, is later burnt in glowing combustion and produces methyl chloride. This air is entrained into the convection column and transported to at least tropopause levels. The results of the various production processes are shown in Table 2.

Taking account only of documented fires, I estimate the production of methyl chloride in the USA by burning cellulose and PVC averages 210,000 t yr^{-1}. The requirement that ClX be produced during glowing combustion may be overly stringent and the estimate may be 40% too low. The rate of production by this source has been estimated to be 5.2×10^6 t yr^{-1} (ref. 26). For instance, current estimates are that half of the timber cut in the world is used for firewood[27]. Forest fire wood and agricultural burning has been a common practice throughout the world for many thousands of years, swamping the US ClX production. If Eckholm's estimates[27] of forest depletion are correct, by the year 2000 there will be a significant decrease

Table 1 Recent US yearly production of polyvinyl chloride and estimated release of methyl chloride

Year	PVC production (Mt yr^{-1})*	Methyl chloride produced from PVC burnt in waste (t yr^{-1})	Methyl chloride from building fires (t yr^{-1})	Total methyl chloride (t yr^{-1})
1965	8.006	26,020	24,018	50,038

Modelling climatic response to orbital parameter variations

ACCORDING to the astronomical or Milankovitch theory, the glacial fluctuations of the Pleistocene are the climatic response to secular variations in the obliquity, eccentricity, and longitude of perihelion of the Earth's orbit. Variations in these orbital parameters during the past several hundred thousand years can be computed with great precision[1], and the resulting changes in incident radiation at the top of the atmosphere are easily obtained. If one can predict the climatic response to perturbations in incident radiation, one can, therefore, test the Milankovitch theory by comparing the predicted climatic changes with those inferred from the geological record. No other theory of the ice ages admits such a straightforward check on its validity. We have made a preliminary attempt at verifying the Milankovitch theory using a zonally symmetric energy-balance climate model forced with seasonally varying insolation and obtain generally favourable results.

The model predicts, as functions of latitude and time of year, the temperatures of two atmospheric layers (representing the upper and lower halves of the troposphere), surface temperatures over land and ocean, the depth of snow over land, and the sea ice thickness. A radiative transfer model similar to that of Manabe and Wetherald[2] is used to compute radiative heating rates in the two atmospheric layers and the net flux at the surface. Cloudiness and relative humidity are assumed to be fixed and independent of latitude in the radiative calculation. Heat is transferred meridionally by linear diffusion in the atmosphere.

This crude atmospheric model is coupled to the land and ocean surfaces through simple boundary layers. The ocean temperature is assumed to be that of a 40-m deep isothermal layer of water, and the land temperature that of a water-saturated surface with no heat capacity. No heat is transported by the model's 'ocean'. Ocean temperatures are not allowed to fall below 273 K, at which temperature sea ice is assumed to form. Sea ice thickness and temperature are predicted with a
Fig. 1 The model's 'palaeoclimatic record' for the past 150,000 yr is shown in the upper figure. *a*, Four points are plotted for each experiment, corresponding to the seasonal limits of land snowcover (hatching) and sea ice (cross hatching) in the Northern Hemisphere. The northermost point represents the minimum (summer) extent of snowcover on land. North of this latitude, snow is free to accumulate from year to year; we therefore identify it with the extent of continental glaciers. The other three points (from north to south) represent the minimum extent of sea ice, the maximum extent of sea ice, and the maximum extent of snowcover over land. Changes in snowcover and sea ice extent predicted by the model in the Southern Hemisphere are much smaller than these changes in the north. ('Arctic Ocean' refers to latitudes at which there is no land.) *b*, A plot of palaeo-temperatures inferred from faunal abundances (of North Atlantic plankton) in a deep-sea core in the North Atlantic[6]. Its gross features are consistent with other palaeoclimatic reconstructions of this period. Three warm peaks separated by ∼ 20,000 yr mark the last interglacial. The rapid descent into the Wisconsin ice age occurs at ∼ 70,000 yr BP, followed by a period of relatively warm climate (middle Wisconsin), then by the late Wisconsin glacial maximum, and finally by the warmth of the Holocene.

scheme very similar to that used by Bryan[3]. It is also assumed that snow falls at a fixed rate, dependent only on latitude, whenever the surface temperature falls below 273 K. Snowmelt and snowdepth are then computed in a straightforward manner. Surface albedos are chosen to be 0.1 over bare land and open water, and 0.7 over snow-covered land and sea ice. Zonally symmetric atmospheric heating rates are obtained by combining the predicted rates over land and ocean in proportions determined by the fraction of land around a latitude circle.

The model is similar to diffusive energy-balance models used by Sellers[4] and North[5], with changes in surface albedos having a dominant role in determining the sensitivity to changes in external forcing.

For a given set of orbital parameters, we compute the flux of solar radiation incident at the top of the atmosphere as a function of latitude and time of year. The model's equilibrium response to this pattern of insolation is then obtained by integrating its equations of motion until a steady state is achieved. The results of such computations for the present orbital parameters and for those at 5,000-yr intervals into the past (for the past 150,000 yr) are summarised in Fig. 1a. Figure 1b (reproduced from Sancetta, Imbrie, and Kipp[6]) is a plot of a faunal index obtained from counts of planktonic foraminifera in a single deep-sea core in the North Atlantic. The index is calibrated to be an estimate of summer sea-surface temperatures in °C.

The largest difference in mean Northern Hemisphere surface temperature between any two of the experiments described in Fig. 1a is 2.4 K. Changes in mean Southern Hemisphere surface temperatures are smaller—at most 0.4 K.

The model is particularly sensitive to insolation anomalies during the Northern Hemisphere summer, with high obliquity (large seasonal variation) and perihelion near Northern Hemisphere summer solstice producing the warmest climates. During the summer, when land surface temperature gradients are small and incident solar radiation is large, changes in temperature produce the largest displacements of the snow margin, and the resulting changes in albedo produce the largest changes in absorption of incident radiation. The Southern Hemisphere, with less land and a smaller seasonal variation, is not as sensitive to the seasonal redistribution of insolation. This sensitivity to summer insolation in the Northern Hemisphere is consistent with Milankovitch's assumptions, and the time evolution predicted by the model is similar to his summer insolation curves for high latitudes in the Northern Hemisphere[7]. The reader is referred to the literature[8,9] for a detailed comparison of the Milankovitch curves with the geological record.

Large discrepancies between the model and the record of the recent past are evident from Fig. 1. For the present values of the orbital parameters, the model gives a climate intermediate between a predicted glacial minimum at 10,000 yr BP and a glacial maximum at 25,000 yr BP, while observations place the present climate much closer to the most recent climatic optimum at ~ 5,000 yr BP. This discrepancy may arise from other sources of variability, or from a lag resulting from the time required to change the temperatures of abyssal waters or to build and destroy continental glaciers, or to other model deficiencies which may tend to overemphasise the importance of summer insolation anomalies in the Northern Hemisphere.

In spite of such discrepancies, Fig. 1 suggests that a substantial portion of climatic variability on these time scales can be understood as the equilibrium response to perturbations in the orbital parameters. Quantitative tests with more convincing climate models are needed to confirm these very preliminary results. If this theory is correct, the palaeoclimatic record becomes an invaluable source of information on climatic sensitivity.

Ultraviolet absorption by metal–ammonia solutions

By pulse radiolysis of aqueous solutions at room temperature, new absorption bands for H, OH, D, OD and e_{aq}^- in the ultraviolet region down to 188 nm have been observed[1,2] and recently confirmed[3]. The favoured interpretation was a redshift of the absorption band of water caused by perturbation by the solutes (H, D, e_{aq}^-) similar to the β-band displacement in alkali halide crystals[1]. It was also suggested that such a band may exist in liquid ammonia, implying that it is a general phenomenon associated with the solvated electron. Furthermore, the transient spectrum obtained by pulse radiolysis of pure liquid ammonia (-45 °C) shows, in addition to the broad infrared absorption of the solvated electron, two unidentified bands in the ultraviolet region[4]. To study optical properties in this range, we chose metal–ammonia solutions which are relatively stable although their decomposition leads to the amide ion which itself absorbs strongly in the same region. Our findings strongly support the hypothesis, though amide and hydrogen are the only products and have been thoroughly studied.

The solutions were prepared taking care to ensure that the reagents were sufficiently pure to avoid their catalytic decomposition. We used pressure-resistant cells with Suprasil windows[5]. To account for the small difference between the optical paths of the sample and reference cells which could cause some solvent absorption in the ultraviolet region, we systematically recorded the base line with pure ammonia in both cells. To record the spectra for a wide range of alkali metal concentrations, various optical path lengths from 10^{-2} to 10 mm were used.

The temperature was varied by a current of cold nitrogen gas and we checked that thermal equilibrium was reached before recording the spectrum, otherwise the shift of the solvent

Fig. 1 Experimental results for the dependence of the extinction coefficient on wavelength. For potassium–ammonia solutions: ●, -50 °C, 2.35×10^{-3} mol l^{-1}, path length 1.90 mm; ○, 20 °C, 2.03×10^{-3} mol l^{-1}, path length 1.90 mm; ■, -50 °C, 7.3×10^{-4} mol l^{-1}, path length 10.0 mm; □, 20 °C, 6.3×10^{-4} mol l^{-1}, path length 10.0 mm. The results are normalised relative to $\varepsilon_{e^-}{}_{am, 700, 20 °C} = 1,575$ l mol^{-1} cm^{-1} and $\varepsilon_{e^-}{}_{am, 700, -50 °C} = 2,600$ l mol^{-1} cm^{-1}. Dashed curves: amide spectra; *a*, -50 °C; *b*, 20 °C. $\varepsilon_{NH_2^-, 348, 20 °C} = 2,600$ l mol^{-1} cm^{-1}; $\varepsilon_{NH_2^-, 330, -50 °C} = 3,040$ l mol^{-1} cm^{-1}. Results are mean values for the concentration range 5×10^{-4}–2×10^{-3} mol l^{-1}.
band with temperature results in a pseudo absorption within the studied range. Spectra were recorded with Beckman ACTA IV M and Beckman DK-1A spectrophotometers flushed with nitrogen gas.

At low temperature ($-50\ ^\circ$C) the rate of decomposition is usually negligible but at room temperature the reaction is catalysed by the walls, especially when using the thin cells for which the surface-to-volume ratio is very high. The absorbances were first followed kinetically for a short time in the infrared band of e_{am}^-, for instance at 700 nm, and at the maximum of the amide absorption, $\lambda = 348$ nm (20 $^\circ$C). These measurements revealed the extent to which decomposition occurred during the recording and when necessary allowed the spectra to be corrected.

We examined many more or less stable solutions. The results presented Fig. 1 correspond to the best runs. The optical densities were normalised at 700 nm and the shape of the infrared spectra between 500 and 800 nm at 25 $^\circ$C and between 700 and 1,000 nm at $-50\ ^\circ$C agree with those found previously[4,6].

The spectra normalised relative to A_{700} were plotted assuming an extinction coefficient at 700 nm $\varepsilon_{e^-_{am,700}} = 1,575$ l mol^{-1} cm^{-1} at 20 $^\circ$C, and $\varepsilon_{e^-_{am,700}} = 2,600$ l mol^{-1} cm^{-1} at $-50\ ^\circ$C (refs 4 and 6). It appears (Fig. 1) that the spectrum consists of a second band in the ultraviolet superposed on the tail of the large infrared band and that no characteristic absorption of NH_2^- is present. Only at room temperature and at a potassium concentration of 2×10^{-3} mol l^{-1} was a weak amide band present, but its contribution was easily subtracted since the amide spectrum is accurately known down to 230 nm (Fig. 1)[7,8]. Even when the amide absorption increases with time, the kinetics show that the absorption at 348 nm and 230 nm increases with the decay of the infrared band (isobestic point at 402 ± 2 nm). But the increase in the ultraviolet absorption is not at all that expected from the amide spectrum. This means that a part of the ultraviolet absorption should be attributed to e_{am}^- and so the apparent extinction coefficient ($\varepsilon_{NH_2}^- - \varepsilon_{e_{am}}^-$) enables us to determine corresponding $\varepsilon_{e_{am}}^-$ values in this region. These are in good agreement with those deduced from direct observation of undecomposed solutions (see below). This method of subtracting the amide spectrum is the only one which can be applied to high concentrations ($\sim 10^{-2}$ mol l^{-1}), for which the decay is rapid. In this case the same spectrum was obtained, indicating that ultraviolet absorption occurs when the electron is clearly associated with ion aggregates.

We note, for the best runs presented in Fig. 1, that the results agree for both concentrations, that is 6.3×10^{-4} mol l^{-1} at 20 $^\circ$C (optical path 10 mm) and 2.0×10^{-3} mol l^{-1} at 20 $^\circ$C (optical path 1.9 mm), showing that the ultraviolet absorption is well correlated with the infrared absorption of e_{am}^-. Comparing the spectra of the same solutions at room and low temperature, Fig. 1 shows that the blueshift of the wide infrared band is still observed in the plateau region (300–400 nm) resulting in values

$$\varepsilon_{350,\ 20\ ^\circ C} = 300 \pm 30\ \text{l mol}^{-1}\text{cm}^{-1}$$

and

$$\varepsilon_{350,\ -50\ ^\circ C} = 390 \pm 30\ \text{l mol}^{-1}\text{cm}^{-1}$$

At lower wavelengths, we observe absorptions merging into the solvent band as in the case of e_{aq}^-

$$\varepsilon_{245,\ 20\ ^\circ C} = 950 \pm 100\ \text{l mol}^{-1}\text{cm}^{-1}$$

and

$$\varepsilon_{240,\ -50\ ^\circ C} = 1,400 \pm 100\ \text{l mol}^{-1}\text{cm}^{-1}$$

The ultraviolet absorption from the solvated electron in liquid ammonia increases at $\leqslant 280$ nm while the solvent absorption only starts to rise at $\leqslant 230$ nm. In water the respective values are 220 nm and 180 nm. Although it may not be

decisive, this correlated displacement supports Hart's interpretation that the redshift of the absorption band of the solvent molecules is caused by perturbations attributable to the electron.

This conclusion is strengthened by the observed temperature effect. Indeed, Fig. 1 shows that the ultraviolet absorption of the ammonia solution starts at higher wavelengths at 20 $^\circ$C than at $-50\ ^\circ$C as is the case for the band of the pure solvent itself which exhibits a blueshift of ~ 7 nm when the temperature is lowered over the same range (to be published).

If we admit the above interpretation, the extinction coefficient in the ultraviolet range is not a direct characteristic of the solvated electron but is a parameter determined by the molecules in the solvation shell. In the semi-continuum model[9-11], one must take into account interactions which become weaker with successive layers around the electron. The observed ultraviolet absorption is an averaged sum of the perturbations of transitions of these solvent molecules.

A rough approximation which assures the involvement of a limited number of solvent molecules in the solvation sphere of the electron, four for example, leads to extinction coefficients four times smaller than those indicated experimentally. The band obtained is similar to that of the pure solvent and the shift (~ 27 nm) gives a magnitude of the energy of the perturbation of ~ 0.6 eV.

Rainfall characteristics in eastern Sahel

THE recent drought conditions in the Sahel region of Africa have generated studies of long term trends in rainfall and monthly or seasonal atmospheric conditions related to the area[1-5]. The results of these studies, in general, indicate no specific trends in precipitation[3], and some evidence of direct[1] and/or long distance[5] relationships between monthly or seasonal atmospheric state and Sahelian rainfall. We present here the results of a study which suggest the major factor affecting rainfall during the drought was a change in easterly wave activity over northern tropical Africa.

The occurrence and characteristics of easterly waves over northern tropical Africa have been discussed by others[6-8]. In relation to easterly waves and precipitation, Burpee[8] has shown that modulation of rainfall in the region between 0 and 18 $^\circ$W is related to wave passage. He found no clear evidence, however, of a similar wave–rainfall relationship between 0 and 15°E. In the Sudan, Hammer[9] found that spatial and temperal patterns of rainfall approximated the 4–5-d period commonly associated with easterly waves. From evaluation of weather satellite imagery, it has been estimated that 90% of the occurrence of widespread heavy rainfall is directly related to easterly wave passage[10].

To define more clearly the characteristics of Sudanese rainfall, daily cumulative rainfall totals from 200 stations
Fig. 1 *a*, Power spectrum analysis results for 90-d period June 13–September 10, 1953 (—), 1961 (·····) and 1969 (————). *b*, As in *a* for 1968 (·····), 1970 (——) and 1971 (————).

in the Sudan were analysed using power spectral techniques. About 75%, a higher proportion in the latter years, were stations located north of 11°N or zonally equivalent to the main drought area of Africa. Unfiltered precipitation totals between June 13 and September 10—the main portion of the rain season—for 1953, 1961, 1968, 1969, 1970 and 1971 were used in the analyses. The spectral analyses were carried out using the OS-3 ARAND system routine SPECT 1 of Oregon State University, and the results are shown in Fig. 1*a* and *b*. The bandwidth used was 0.031 cycle d⁻¹.

Figure 1*a* presents the spectral curves for the years 1953, 1961 and 1969. 1953 and 1961 were years of average to above average rainfall for most of the Sudan during the months of study. The factor accounting for most of the variance in the spectra of 1953 and 1961 was the movement of the so-called Intertropical Convergence (ITC) as shown by the high values at 1 cycle per 90 d (0.011 cycle d⁻¹). For these two years, major varience is also contained within the period 3.7–5 d (0.27–0.20 cycle d⁻¹). This corresponds to the most frequently cited period associated with easterly wave activity. 1969 had a somewhat enigmatic rain season in that in spite of being in the drought sequence, rainfall was near normal in the Sudan. This was similar to precipitation conditions during 1969 in western and central Africa, as found[3,4,11] from integrated station data. The

small amount of variance contained under the 1 cycle per 90-d portion of the curve for 1969 probably reflects the stagnation of the ITC in July, which limited rainfall over the northern half of the Sudan. Because of the restricted effect of the ITC on the 1969 spectrum, caution must be used in interpreting the variance accounted for under the 3.7–5-d portion of the spectrum as being as relatively significant as it seems compared with 1953 and 1961. A frequency domain test was carried out using the OSU OS-3 ARAND system routine NOIZT to determine if each of the time series could be considered 'white noise'. All five peaks on Fig. 1*a* were significant at the 95% level, indicating they were not the result of a purely random process.

In comparison with the three years already discussed, 1968, 1970 and 1971 display a very different spectral pattern (Fig. 1*b*). Although ITC movement in 1970 was statistically significant (evaluated by the NOIZT routine), the remainder of the spectra for the three years are notably less peaked and temporally coincident than those of Fig. 1*a*, with the exception of a possible 20–40-d period in 1968. Rainfall amounts recorded in the Sudan were markedly below average during 1968, 1969 and 1970. Of the nine months, which comprised most of the 90-d period analysed during these three years, five months had 51–75% of the stations with below average monthly rainfall and two additional months with 46–50% of the stations reporting less than average precipitation. The overall appearance of Fig. 1*b* presents a more random peak occurrence pattern than Fig. 1*a*, particularly in the shorter periods. The rainfall of the three dry years thus seems to be responding to a fluctuating rainfall producing mechanism, in contrast to the relatively constant short period pulses of the more humid years.

Visual evaluation of weather satellite imagery of July and August for 1969, 1970 and 1971 confirms the variability of wave conditions over north-eastern tropical Africa (unpublished). Easterly wave-associated cloud pattern passage intervals were notably different during the three years. 1969 had a reasonably consistent 4–5-d period between wave occurrences; in 1970, most waves were spaced at 2–3 d intervals, with an occasional intervening 5-d period between waves: and 1971 was the most erratic year in terms of the period of the occurrence of the wave. Wave periods ranged from 2–9 d, with 2-d spacing most common. For all three years ~ 65% of the waves were conservative for 1–4 d and could be followed from over the Sudan to central Africa, where the satellite tracking used in this study terminated.

Within the Sudan, the drier rain seasons seem to experience rainfall events in a more spasmodic fashion than wetter rain seasons, and major rainfalls are related to easterly wave passage. In addition, the Sudan lies 'upstream', in terms of easterly wave activity, of the western and central African drought areas and there has been generally synchronous rainfall during recent years between the various regions. Thus, there seems to be a strong probability that during the recent drought the easterly wave operated in an unusual manner, with a consequent reduction in rainfall. The intra- and/or extra-wave factors related to modification of wave conditions over continental Africa are still in question.

Deep-sea bottom photographs show that benthic organisms remove sediment cover from manganese nodules

MARINE geologists, geochemists, biologists and other oceanographers have studied manganese nodules since they were first reported by Murray and Renard[1] in 1891. Much has been learned (see ref. 2 for a recent review) but many

Fig. 1 Bottom photographs from the manganese nodule province of the North Equatorial Pacific Ocean. A polyplacophoran (*Chiton*) has removed sediment cover from through nodules (*a*) and has almost cleaned the nodule it is on arrowed. Note the sediment covering adjacent nodules. Another *Chiton* (*b*) is feeding on nodule surface. Average nodule in this area is 6–8 cm in maximum length.
aspects of their formation and growth are open to question. The Environmental Research Laboratory of the National Oceanic and Atmospheric Administration has sponsored a multi-university, multi-disciplinary investigation to determine the environmental impact of manganese nodule mining. As part of the benthic baseline study of the Deep Ocean Mining Environmental Survey (DOMES), approximately 10,000 bottom photographs have been taken. I wish to report a close examination of 365 prints taken on one lowering of the camera near latitude 14°17.5′N, longitude 126°15.4′W at a depth of about 4,500 m.

The following epibenthonts were recognised: 99 cidaroid echinoids; 45 ophiurad ophiuroids; 32 elasipod holothurians; 21 actiniarid zoantharia; 8 pennatulid anthozoans; 5 bryozoans; 4 gorgonid anthozoans; 4 asteroids; 3 porifera; 3 lepidopleurinid polyplacophora; 2 pycnogonida; 2 brachyuran crabs, and one each crinoid, ascidacean and gastropod. The area of each photograph was calculated using the average size of nodules collected at that station as a scale. The average size was 7.4 cm (± 0.7), and it was determined that 3,031 m^2 (± 303) were seen, taking into account the few frames where overlapping occurred. Consequently the epifaunal density is 0.08 organisms per m^2 (± 0.008), which agrees with photographic survey conducted under the oligotrophic Sargasso Sea at similar depths[3].

Animal activities such as burrowing under nodules and pushing them upward or ingesting nodules and subsequently egesting them have been suggested[4] as methods by which the geologically older nodules are kept on top of the younger surficial sediments. These operations may well take place and I would now like to add the mechanism whereby some benthic animals remove sediment from the surface of manganese nodules, apparently as part of their feeding activity. Almost every frame shows evidence of uneven sediment cover on adjacent nodules. In seven frames there are organisms which I believe are grazing and are associated with cleaner nodules (that is, covered with less sediment). The clearest of these photographs are presented here (Figs 1–3). Polyplacophora (chitons) are commonly found in the rocky, intertidal zone where they eat by scraping algae and other material from the rocks[5]. Since manganese nodules are commonly covered with structures of biological origin[6,7] it is not difficult to hypothesise that chitons in a nodule province feed by removing organic material from nodule surfaces (Fig. 1*a* and *b*). Phanerozonid asteroids

Fig. 2 Bottom photograph of phanerozonid asteroid (starfish) feeding on and cleaning manganese nodule surface.
Fig. 3 Bottom photograph of elasipod holothurian (sea cucumber, arrowed). The meandering trail of darker nodules that starts in the upper right corner and ends at the holothurian indicates its path and the removal of sediment cover from nodules as it feeds on deposits.

(Fig. 2) eat various foods[5] and also seem to scrape and clean nodules. Elasipod holothurians are deposit feeders (Fig. 3) and in addition to possibly nudging nodules and keeping them at the sediment–water interface, they ingest sediment from the nodule surface.

Although the sedimentation rate in this area is low[9], sediment redistribution is continually taking place. It is not possible to estimate the rate of either cleaning or bottom redispersion of sediment, but it is evident from these photographs that periodic cleaning takes place. If nodules grow on their upper surfaces this episodic cleaning may help to explain their intermittent growth.

I thank W. S. Broeker and P. Biscaye for discussions, and the Environmental Research Laboratory of NOAA for support.

Sulphonium analogue of lecithin in diatoms

PHOSPHATIDYL choline (lecithin) is the most widespread of the phospholipid membrane components of eukaryotic cells, being present in virtually all those investigated so far. The exceptions noted until recently have been blue-green algae[1], the yeast-like fungus *Pullularia pullulans*[2] and the phytoflagellate, *Ochromonas danica*[3]. We report here a sulphonium analogue of phosphatidyl

choline which completely replaces lecithin in the non-photo-synthetic diatom, *Nitzschia alba*[4]. The new phospholipid is a phosphatidyl *S,S*-dimethyl mercaptoethanol (phosphatidyl sulphocholine) with the following structure:

$$
\begin{array}{l}
\overset{\overset{O\;O^-}{\underset{||}{\diagup}}}{H_2C-O-P-OCH_2CH_2S(CH_3)_2^+} \qquad R_1, R_2 = \text{acyl chains}\\[2mm]
\;\;\mid\\
H-C-O-CO-R_1\\[2mm]
\;\;\mid\\
H_2C-O-CO-R_2
\end{array}
$$
The lipid was first observed on thin-layer chromatograms of the total lipids of *N. alba* (grown in synthetic seawater[4]) as a major component with mobilities and staining behaviour[5] similar to those of lecithin (Fig. 1). But no glycerophosphorylcholine was detected on mild alkaline deacylation of the total lipids, indicating that lecithin was absent in this organism. The new lipid appeared to be a phosphosulpholipid by its labelling with both ^{35}S and ^{32}P when cells were grown in medium containing ^{35}S-sulphate and ^{32}P-phosphate.

The phosphosulpholipid was isolated in pure form by column chromatography of the total lipids on Biosil A silicic acid, using increasing concentrations of methanol in chloroform as eluting solvents. The sulpholipid appeared in the chloromethanol 1:3 eluate and after precipitation from chloroform by addition of acetone, it was chromatographically pure. It accounted for 68% of the total lipid phosphorus and had elemental analyses consistent with those expected for a sulphonium analogue of lecithin. We found C, 64.18%; H, 9.25%; N, 0.00; S, 4.25%; P, 3.85%, atomic ratio P/S, 0.94. The calculated values for $C_{41.9}H_{73.8}O_8SP$ (768.73) are C, 65.47%; H, 9.68%; S, 4.17%; P, 4.02%, P/S, 1.00.

The analysis showed the complete absence of nitrogen and the presence of sulphur and phosphorus in an atomic ratio close to 1:1. Fatty acid analysis by gas–liquid chromatography (GLC) on 10% butanediol succinate polyester at 180 °C revealed the presence of 14:0 (30%), 16:0 (8%), 18:1 (12%), 18:2 (8%), 20:5 (27%) and 22:6 (4%) acids, permitting calculation of the molecular formula given above.

The nuclear magnetic resonance (NMR) spectrum of the

Fig. 1 Thin-layer chromatogram on silica gel H in the solvent system chloroform–methanol–28% ammonia (65:35:5, v/v) of: *a*, total lipids of *N. alba*; *b*, isolated phosphatidyl sulphocholine from *N. alba*; *c*, commercial egg lecithin (PC), and *d*, mixture of phosphatidyl sulphocholine and lecithin. Chromatogram was charred with 50% H_2SO_4. Phospholipids were detected by the phosphate stain[5] and "choline-"containing lipids by the Dragendorff reagent[5]. NL, Neutral lipid; CS, ceramide sulphonate[6]; MGD, monoglycosyl diglyceride; SS, sterol sulphate[6]; PG, phosphatidyl glycerol; SQD, sulphoquinovosyl diglyceride; DGD, diglycosyl diglyceride; SPL, phosphatidyl sulphocholine; PI, phosphatidyl inositol; LSPL, lysophosphatidyl sulphocholine. SPL and LSPL as well as lecithin gave positive tests with the phosphate and "choline" stains.

close similarity except for the sharp peak at 970 cm^{-1} which was absent from the spectrum of the sulpholipid and which is generally assigned to the $(CH_3)_3N^+$ group of lecithin[8,9].

Enzymatic hydrolysis of the sulpholipid with cabbage phospholipase D yielded: (1) a chloroform-soluble phospholipid identified as phosphatidic acid by cochromatography on silica gel H with an authentic standard (R_f, 0.05 and 0.9 in chloroform–methanol–28% ammonia (65:35:5, v/v) and chloroform–methanol–90% acetic acid (30:4:20, v/v), respectively); and (2) a water-soluble sulphur-containing compound which gave a positive Dragendorff reaction[5] and had mobilities on paper chromatography and paper electrophoresis (Table 2) identical to those of synthetic 2-hydroxyethyl dimethylsulphonium iodide (*S,S*-dimethyl mercaptoethanol, "sulphocholine", made by methylation of mercaptoethanol with methyl iodide). The latter product was also present in the 2.5% methanolic-HCl hydrolysate of the sulpholipid along with fatty acid methyl esters and two water-soluble periodate–Schiff-positive products identified chromatographically as α-glycerophosphate and methyl-α-glycerophosphate. Identification of the sulphur-containing acid-hydrolysis product as "sulphocholine" was confirmed by monodemethylation of the sulphonium group with sodium benzenethiolate[10]. The reaction products had GLC retention times relative to dimethylsulphide (4.59 and 6.04) identical to those of authentic hydroxyethylmethyl sulphide and phenylmethyl sulphide, respectively, on a column of 10% butanediolsuccinate polyester on Gaschrom W at 128 °C and a carrier inlet pressure of 0.4 kg cm^{-2}. An identical gas chromatographic tracing was obtained after monodemethylation of synthetic "sulphocholine".

Hydrolysis of the sulpholipid with phospholipase C from *Clostriduim perfringens* released: (1) a chloroform-soluble product with R_f value identical to that of standard 1,2-diglyceride (R_f, 0.22 on silica gel H in petroleum ether–diethyl ether–acetic acid 70:30:1, v/v); and (2) a water-soluble phosphorus and sulphur-containing compound with mobilities similar to those of phosphorylcholine (Table 2). Unlike phosphorylcholine, however, the water-soluble product was found to undergo methanolysis in methanolic 0.2 N NaOH at 37 °C for 1 h, with quantitative release of inorganic phosphate and formation of methoxysulphocholine (2-methoxyethyl dimethylsulphonium salt) identified chromatographically and electrophoretically in comparison with an authentic standard (Table 2). The water-soluble product formed by phospholipase C hydrolysis is thus probably phosphorylsulphocholine.

Mild alkaline deacylation of the phosphatidyl sulphocholine in methanolic NaOH also yielded methoxysulphocholine, together with α-glycerophosphate (Table 2) instead of the expected glycerophosphoryl sulphocholine. Apparently the phosphate-sulphocholine linkage both in phosphatidyl sulpho-

sulpholipid showed a sharp signal at 3.17 δ p.p.m. which was assigned to the six protons of the dimethyl sulphonium group. For comparison, the quaternary ammonium group methyl protons of phosphatidyl choline gave a singlet at 3.37 δ p.p.m. (Table 1; ref. 7). The remainder of the spectrum was essentially the same as that of phosphatidyl choline. Assignments of proton signals and their integration (Table 1) are consistent with the structure of phosphatidyl *S,S*-dimethyl mercaptoethanol. The infrared spectrum of the sulpholipid showed peaks at 2,868 and 2,968 cm^{-1} (CH_2 and CH_3), 1,747 cm^{-1} (ester C = O), 1,475 cm^{-1} (CH_2 and CH_3), 1,285 cm^{-1} (P = O), 1,175 cm^{-1} (ester C–O) and a doublet with a major peak at 1,092 cm^{-1} (PO$^-$) and a shoulder at 1,065 cm^{-1} (P–O–C). There was no evidence of sulphate (1,440–1,350, 1,230–1,150 cm^{-1}) or sulphonate (1,420–1,330, 1,200–1,145 cm^{-1}) bands. Comparison with the spectrum of phosphatidyl choline revealed

Table 2 R_f values and electrophoretic mobilities of the sulphur-containing hydrolysis products from phosphatidyl sulphocholine

*Relative to mobility of choline.
†Hydrolysed in 2.5% methanolic HCl for 5 h under reflux; water-soluble phosphates detected were glycerophosphate and methylglycerophosphate (R_f in butanol–propionic acid–water 142:71:100, v/v: 0.17 and 0.30, respectively).
‡According to procedure of Kates[5], neutralised with ethyl formate; the water-soluble phosphate detected was α-glycerophosphate (R_f 0.17 and 0.31 in butanol–propionic acid–water 142:71:100 (v/v) and phenol–water 100:38 (w/w) respectively).

choline and in phosphorylsulphocholine is readily attacked by methoxide ion, resulting in the release of the methoxysulphocholine with concomitant formation of α-glycerophosphate or inorganic phosphate, respectively.

The anomalous behaviour of phosphatidyl sulphocholine towards mild alkali may explain the unusual phospholipid composition of several photosynthetic marine diatoms reported previously[11]. Low amounts of glycerophosphorylcholine (3–8%) and high amounts of α-glycerophosphate (11–32%), as well as a ^{35}S-labelled compound (ref. 11, Fig. 8, spot 11) with mobilities similar to those of methoxysulphocholine, were detected in mild alkaline hydrolysates of the total lipids of these diatoms. Also, a ^{32}P-labelled and ^{35}S-labelled spot with the mobilities of lecithin was detected on chromatograms of the intact lipids of these organisms, indicating the presence of phosphatidyl sulphocholine (ref. 11, Fig. 1 and 7).

From these observations and the findings reported here, it seems that phosphatidyl sulphocholine may be present in high proportions in marine diatoms, replacing phosphatidyl choline as the major membrane phospholipid component. Phosphatidyl sulphocholine would be expected to have a zwitterionic structure at pH 7 and overall size and shape similar to lecithin so that this novel lipid could functionally substitute for lecithin in membranes of N. alba and other diatoms.

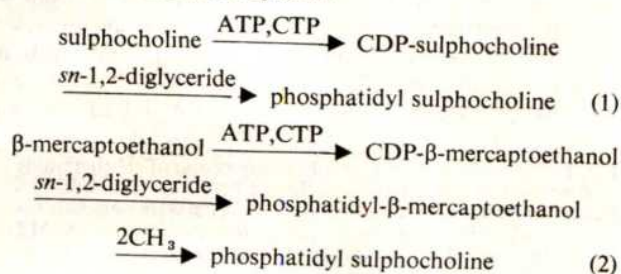
The question concerning the biosynthetic pathways for the sulphonium analogue is intriguing, and two possible pathways can be postulated by analogy with those for phosphatidyl choline in mammalian and plant systems[12]

$$\text{sulphocholine} \xrightarrow{\text{ATP,CTP}} \text{CDP-sulphocholine}$$

$$\xrightarrow{\textit{sn}\text{-1,2-diglyceride}} \text{phosphatidyl sulphocholine} \quad (1)$$

$$\beta\text{-mercaptoethanol} \xrightarrow{\text{ATP,CTP}} \text{CDP-}\beta\text{-mercaptoethanol}$$

$$\xrightarrow{\textit{sn}\text{-1,2-diglyceride}} \text{phosphatidyl-}\beta\text{-mercaptoethanol}$$

$$\xrightarrow{2CH_3} \text{phosphatidyl sulphocholine} \quad (2)$$


In pathway (1), sulphocholine might be derived from dimethyl β-propriothetin, which is commonly found in marine organisms[13–15] and has been shown to be derived from methionine[14]. Alternatively, the sulphocholine might arise from methylation of β-mercaptoethanol, which is known to be a substrate for methyltransferases in rat liver[16]. Evidence for the operation of pathway (1) has been reported for a mammalian system by Bjerve and Bremer[17] who found that radioactive label from both ^{35}S-sulphocholine and Me-^{3}H-sulphocholine was incorporated in rat heart and kidney phospholipids. With regard to pathway (2), we have not detected the presence of the expected phosphatidyl mercaptoethanol in N. alba, but this would not necessarily eliminate pathway (2) because rapid turnover of the thiol intermediate would make its detection difficult.

The absence in N. alba and other marine diatoms[11] of significant amounts of nitrogenous phospholipids (phosphatidylserine, phosphatidylethanolamine and phosphatidylcholine) and the high concentrations of phosphatidyl sulphocholine and ceramide sulphonate[6] suggest that in these organisms sulphur-containing amino acids (for example, cysteine and methionine) rather than serine, probably act as primary metabolic precursors of the glycerophospholipids and sphingolipids. These novel biosynthetic pathways are being investigated.

An exosporium-like outer layer in *Bacillus subtilis* spores

BACTERIAL endospores are differentiated cells surrounded by several characteristic spore envelopes—cortex, inner and outer spore coats. In addition to these layers, present in all *Bacillus* and *Clostridium* spores, several species possess a loosely fitting outermost structure—the exosporium[1–5]. In other species, however, including *B. subtilis*, the exosporium has not been found in thin sections[1,6,7], although its possible existence was suggested by the observation of a fibrous 'exosporial' layer by freeze-etching[8]. In our studies of the fine structure of *B. subtilis* spores we have found that a new outer layer, probably an exosporium, is present and can be visualised in thin sections after partial chemical extraction of the spore coats.

PM9, a normally sporulating, auxotrophic (Trp C2, Met C3, Phe A1) strain derived from *B. subtilis* Marburg 168 was used. Spores were obtained in a complex nutrient broth[9] and fixed for electron microscopy either untreated or after incubation for 2 h at 37 °C in 0.1 M Tris, 8 M urea, at pH 8.5 in the presence of 1% mercaptoethanol[10,11]. Fixation, staining and electron microscopy were carried out as described previously[12].

Untreated spores show the classical spore structure with a cortex, an inner coat formed by three well defined layers and a thick, darker outer coat (Fig. 1). After urea–mercaptoethanol treatment (Fig. 2), the cortex and the inner coat remain unchanged, but the outer coat appears more loose and granular. In addition, a loosely fitting single sheet, detached from the

Fig. 1 Untreated free mature spore of *B. subtilis* PM9 exhibiting the typical fine structure of spore envelopes. CX, Spore cortex; IC, inner spore coat; OC, outer spore coat. Note that no exosporium is clearly visible. Bar represents 0.2 μm.
Fig. 2 Free mature spore of *B. subtilis* PM9, treated with urea and mercaptoethanol. The three envelopes visible in the control (Fig. 1) are present. The fine structure of the outer spore coat is disorganised. Note the clearly defined outermost layer which exhibits all the characteristics of an exosporium (EX). Bar represents 0.2 μm.

outer coat, is visible. This layer is very much like the well known exosporium of *B. cereus* and other species[3-5].

Treatment of spores with a reducing agent in the presence of urea is known to liberate a large amount of insoluble, structural proteins from the spore coats[11,12], as reflected in the morphological changes of the coat structure. Our observations suggest the existence of a new, exosporium-like layer, tightly fitting the spore and masked by the dense outer spore coat. In fact, the exosporium is clearly visible in occasional sections of untreated spores, in which it appears tightly fitting the outer surface and remains in most cases undistinguishable from the dark outer coat. The clarity with which the exosporium could be seen, seems to be the result of two effects of the urea–mercapto-ethanol treatment—partial dissolution of the outer coat and loosening of the exosporium.

Similar results were obtained with other wild-type and mutant *B. subtilis* strains. Control experiments show that the treatment which enables visualisation of 'exosporium' does not destroy the viability and heat resistance of the spores. It has been suggested[13] that the exosporium may play a role in the resistance of the spore—that is, against proteases and lytic enzymes. Its presence in *B. subtilis* spores would explain why there is no marked difference between the properties of these spores and those of such species as *B. cereus*.

Demonstration of an exosporium-like structure in *B. subtilis* implies that the classification of bacterial spores into two classes[12], with and without exosporium, is incorrect, and extends the morphological similarity of the spores of various species to the outermost layer.

Bacteriophage P22 lysogenises efficiently at high multiplicities of infection because *Salmonella typhimurium* DNA synthetic capacity is limited

Infections of *Salmonella typhimurium* by wild-type phage P22 generally result in a lytic response at low multiplicities of infection (MOIs) and a lysogenic response at high MOIs[1]. At MOIs above 5, more than 90% of all cells are lysogenised. At an MOI of 3, 45% of the infected cells become lysogens whereas at an MOI of 1, only 23% of the infected cells are lysogenised. The regulation of P22 lysogeny has been studied extensively[1-7]. Three structural genes and a *cis*-active site in the immunity C (*immC*) region are required to establish lysogeny. Interaction of gene *c1* and *c3* products at the *c27* site stimulates the production of the *c2* repressor, and at the same time causes a transient retardation in the expression of lytic genes[1,8]. A mutant of *S. typhimurium*, Pox-1, that channels P22 infections at any MOI to lysogeny with an efficiency of 1.0 has a reduced capacity for both host and viral DNA synthesis[6]. Slowed synthesis of DNA in this mutant results in an over-production of regulatory proteins relative to the levels of viral DNA in infected cells. This, in turn, results in lysogeny at all MOIs. We now propose that the initial decision

Fig. 1 Effects of MOI on rates of incorporation of ³H-thymidine. *S. typhimurium* strain 109 was infected at 30 °C with wild-type P22 at the indicated MOIs. Samples (10⁸ cells) were pulse labelled with 20 μCi of ³H-thymidine[5]. ○, Uninfected control; ×, MOI 3; △, MOI 5; ▲, MOI 10. The dotted line is an arbitrary base line indicating possible levels of host DNA synthesis (see text). Dashed arrows mark the areas between 6 and 15 min after infection.
Table 1 Percentage hybridisation of DNA and RNA from infected cells to P22 DNA

	MOI				
	1	2	3	10	20
(a) DNA–DNA hybridisation	24%	19%	21%	44%	32%
(b) RNA–DNA hybridisation	—	—	1.8%	6.3%	10.3

a, Hybridisation of ^{3}H-thymidine-labelled DNA from infected cells to P22 DNA. ^{3}H-thymidine (200 µCi ml[−1]) was added to strain 109 6 min after infection and the cells were lysed 20 min after infection as described before[11]. Hybridisation to P22 DNA was done by the method of Denhardt[12]. Data are expressed as the percentage of input counts bound to P22 DNA. Values for MOIs of 1 and 2 were corrected for the presence of uninfected cells in those cultures. *b*, Hybridisation of ^{3}H-uridine-labelled RNA from infected cells to P22 DNA. RNA was pulse labelled with ^{3}H-uridine (15 Ci ml[−1]) for 1 min, 8 min after infection of strain 109 by wild-type P22. RNA was prepared and hybridised to P22 DNA by the method of Smith[13].

between lysis and lysogeny in wild-type cells is also a function of the relative amounts of phage DNA and the phage proteins from the *immC* region.

Wild-type cells were infected with wild-type P22 at MOIs of 3, 5, and 10, and the rates of ^{3}H-thymidine incorporation were determined (Fig. 1). The initial decline in incorporation rate during the first 6 min was a result of shutoff of host DNA synthesis. The extent of host shutoff was comparable in the three infections. Phage DNA synthesis is required for both lysis and lysogeny. The areas under the curves between 6 and 15 min represent such synthesis[4]. Incorporation of ^{3}H-thymidine between 15 and 30 min at MOIs 3 and 5 was primarily into cells which were lytically infected. An arbitrary base line of host DNA synthesis rate is drawn at 3×10^3 c.p.m. min[−1]. This is the level seen by Levine and Schott[4], using a phage mutant unable to synthesise DNA. The areas under the curves between 6 and 15 min were integrated to estimate the relative amounts of viral DNA synthesised in the three infections. Total calculated c.p.m. are 9.1×10^4, 7.1×10^4, and 9.0×10^4 at MOIs of 3, 5 and 10, respectively. The ratios of total c.p.m. incorporated (1.29 : 1.0 : 1.28) are different from the ratios of the parental genomes available for replication. These ratios, and the fact that the heights of the three peaks are comparable, suggest that the maximum replication of parental genomes was reached at an MOI of 3 or less.

Table 1*a* shows the results of hybridising DNA from infected cells to P22 DNA attached to nitrocellulose filters. The ratio of percentage hybridisation for MOI 1 to that for MOI 20 is 1.0 : 1.33, and is much different from the ratio of the parental genomes. It is reasonable to suggest that near maximum replication of P22 DNA occurs at an MOI of 1. Moreover, these data support our conclusion that host shutoff does not depend on MOI, for the fraction of DNA that is virus specific is nearly constant.

RNA synthesis did not follow the same pattern as DNA synthesis. Figure 2 shows the incorporation of ^{3}H-uridine pulses into acid-precipitable material. There were almost fourfold differences in both initial decreases and in maximum levels of incorporation seen at MOIs of 3 and 20. Differences in the degree to which host specific transcription was shutoff probably accounts for the variation in incorporation during the first 2–4 min. This makes interpretation of the curves difficult, since each curve represents the sum of host and phage-specific RNA, and the amount of host RNA may be different in each infection.

We determined the amount of viral-specific RNA synthesised 8 min after infection by hybridising RNA from infected cells to P22 DNA. The results are shown in Table 1*b*. As MOI increased, the total incorporation of ^{3}H-uridine decreased (Fig. 2), but the fraction that was virus specific increased. Two conclusions are drawn from these data. First, the synthesis of phage RNA was directly dependent
Fig. 2 Effects of MOI on rates of incorporation of ^{3}H-uridine. Strain 109 was pulse labelled with 40 µCi of ^{3}H-uridine using the same procedure as for ^{3}H-thymidine incorporation[5]. ○, Uninfected control; ×, MOI 3; △, MOI 5; ▲, MOI 10; □, MOI 20.

on MOI. The ratio of the percentage hybridisable counts at MOI 3 to percentage hybridisable counts at MOI 20 is 1.0 : 5.5, close to the ratio of MOI 3 to MOI 20 which is 1.0 : 6.6. Second, because the fraction of RNA that was virus specific increased with MOI, the fraction that was host specific must have decreased. Therefore, the extent of host shutoff after infection was also MOI dependent.

There is no evidence for translational controls in P22 infections. Therefore, increased levels of RNA synthesis at high MOIs should result in increased levels of protein synthesis. We expect the *cl* gene transcript to be among the few species of phage RNA that are made 8 min after infection[1]. The *cl* protein is pivotal in the establishment of lysogeny[1−3,5−8]. If higher MOIs result in enhanced transcription of this gene, then the ratio of *cl* protein to DNA would be increased at higher MOIs. At present, there is no assay for the *cl* protein. Therefore we are restricted to measurements of RNA.

If cells are infected with wild-type P22 at various MOIs, and the percentage of infected cells receiving 3 or more copies of the parental genome is calculated from a Poisson distribution, there is good agreement between these values and the percentage of infected cells that become lysogens. We suggest that in a cell infected with 1 or 2 viral genomes, the rate of DNA synthesis relative to RNA synthesis is sufficiently rapid that not all the viral DNA can be complexed with *cl* protein, and the infection proceeds to lysis. If three or more copies of phage DNA enter a host cell, the rate of production of *cl* protein is sufficient to bind all the DNA and the cell is lysogenised. The dependence of lysogeny on MOI is explained by the limited capacity of the infected cell to make DNA; this is saturated at MOIs near 1. RNA synthesis is not so limited. Therefore, at high MOI,

the ratio of RNA synthesis (and regulatory proteins) to DNA synthesis is enhanced. When the ratio of regulatory proteins to DNA is sufficiently high, infections go to lysogeny. This is achieved at MOIs of 3 and more in P22.

Phage P22 has been classified as a lambdoid phage[9]. Phage λ also shows increased frequencies of lysogeny at higher MOI[10]. We expect that limited DNA synthetic capacity of the infected bacteria accounts for the increased frequencies.

Acquired resistance to infection with *Schistosoma mansoni* induced by *Toxoplasma gondii*

SPECIFIC acquired immunity to *Schistosoma mansoni* in the mouse has only recently been demonstrated definitively[1]. This phenomenon does not occur until 12 weeks after primary infection and has been found to be adoptively transferred only by serum[2]. The induction of so-called 'immunity' to *S. mansoni* has also been reported in mice and hamsters exposed to a wide variety of unrelated organisms and extracts[3-6], but in most, if not all cases it is likely to be nonspecific. Although all of these acquired forms of resistance have been lumped together under the name of immunity, it is probable that the mechanisms of specific and nonspecific resistance are totally different. The present investigation of the effect on *S. mansoni* infection of *Toxoplasma gondii*, an intracellular protozoan parasite which renders mice resistant to a variety of unrelated organisms[7-11], largely by activation of macrophages[12], may clarify the role of nonspecific mechanisms in protection against schistosomiasis.

Swiss albino female mice (18–20 g) were purchased from Carworth Farms, New City, New York, although in one experiment mice were obtained from Flow Laboratories, Rockville, Maryland. *T. gondii* cysts were obtained from the brains of animals infected for 5–6 weeks with the Gleadle strain. Experimental animals were injected intraperitoneally with 10 cysts suspended in 0.2 ml brain emulsion to which penicillin (100 U ml^{-1}) and streptomycin (10 μg ml^{-1}) were added. Similar volumes of brain emulsion from uninfected mice containing antibiotics were injected intraperitoneally into control animals.

Recovery of immature schistosomes (schistosomula) from the lungs was carried out in two separate experiments in groups of eight *Toxoplasma*-infected mice and eight control animals (injected with normal mouse brain emulsion) 2 weeks after the initiation of the protozoan infection. The animals were anaesthetised and exposed percutaneously to 500 cercariae of a Puerto Rican strain of *S. mansoni*[13]. Recovery of schistosomula was carried out on day 6 after infection (the day of maximum recovery for the strain of mice used) as described by Sher *et al.*[1].

For quantitation of adult worms, mice were injected subcutaneously with 20 cercariae of a Puerto Rican strain of *S. mansoni*. Six to eight weeks after infection, groups of 10 animals were anaesthetised and the portomesenteric venous system perfused[14]. In addition, the livers and mesenteric vessels were searched for worms. All worms recovered from each experimental group were washed in normal saline, counted, and the length of the paired worms measured by an ocular micrometer mounted on a dissecting microscope.

In one experiment the worms were washed three times in normal saline, emulsified in a tissue grinder and injected intraperitoneally into four mice to determine whether or not the schistosomes harboured any *T. gondii*. The animals were killed 6 weeks later, their brains examined for cysts, and their sera tested for fluorescent antibodies[15].

Schistosome eggs were counted by digesting the livers removed from *Toxoplasma*-infected and control mice 8 weeks after infection with *S. mansoni*[16].

In two experiments using mice, respectively, from Carworth Farms and Flow Laboratories, the *Toxoplasma*-infected animals had 35% (61 ± 5 compared with 94 ± 8 in the controls) and 40% (89 ± 10 compared with 148 ± 12 in the controls) reductions in the number of schistosomula recovered 6 d after exposure to *S. mansoni* cercariae. The differences between the experimental and control animals in each case were highly significant ($P < 0.01$).

Table 1 summarises the results of adult worm perfusions 6–8 weeks after *S. mansoni* infection. In two separate experiments, animals infected with *T. gondii* 1 d before exposure to *S. mansoni* developed 32% and 22% fewer total worms, and in each case 50% fewer worm pairs in comparison with controls. The differences in each experiment were significant at the 5% level. Furthermore, measurement

57

of the paired worms in both experiments showed that in each case the female worms from the *Toxoplasma*-infected mice were significantly shorter ($P<0.05$) (Table 1). The effect of the time of induction of toxoplasmosis on the recovery of adult schistosomes was then studied. *Toxoplasma* cysts were injected 4 weeks before and 4 weeks after the initiation of the schistosome infection (Table 1). Whereas previous toxoplasmosis resulted in a 35% reduction in the total worm load, infection 4 weeks after the injection of *S. mansoni* cercariae had no effect.

There was no evidence that the adult schistosomes were infected with *T. gondii* as the four mice injected 6 weeks previously with emulsified worms from *Toxoplasma*-infected animals had no cysts in their brains and no antibodies in their sera.

The results of *S. mansoni* egg counts in the livers of the different experimental groups were as follows: control animals injected with normal brain emulsion developed a mean egg load per liver of $6,736 \pm 325$, whereas animals with *T. gondii* infection induced 4 weeks or 1 d before schistosomiasis had respective reductions in the egg counts of 35% ($4,480 \pm 210$) and 43% ($3,840 \pm 301$). In contrast, animals infected with *T. gondii* 4 weeks after *S. mansoni* had mean egg counts similar to the controls ($6,077 \pm 286$).

Toxoplasmosis has been reported to protect mice against a variety of unrelated organisms and tumours[7-11]. This effect has been ascribed largely to activation of the macrophages[12]. Ruskin *et al.*[12] have demonstrated that activated macrophages from *T. gondii*-infected mice not only display activity *in vivo* but have the capacity *in vitro* to destroy nonspecific target cells by a mechanism which does not involve phagocytosis. It has also been shown that other intracellular infectious agents such as *Besnoitia jellisoni* confer similar properties on mouse peritoneal macrophages[11].

Schistosomiasis is one of the major helminth infections of mankind, and greater understanding of the host defence mechanisms is urgently needed. The variety of conditions discussed under the blanket heading of immunity, however, tends to be confusing. Only recently has it been demonstrated definitively that specific acquired resistance to re-infection occurs in mice previously infected with *S. mansoni*. This does not occur until 12 weeks after infection and has been transferred passively with serum but not with cells[1,2]. Using monospecific antieosinophil serum[17] it has been shown that this form of resistance is due to an anti-body-dependent cell-mediated mechanism in which the effector cell is the eosinophil[18].

Also considered under the term immunity have been various forms of resistance induced by snail haemolymph[3], monkey erythrocytes[4], formalin-killed *Escherichia coli*[5] and extracts of *Fasciola hepatica*[6]. It seems probable, however, that most, if not all of these materials induced a nonspecific form of acquired resistance involving mechanisms totally different from that of specific immunity. The present experiments in which *T. gondii* induced resistance in mice to *S. mansoni* strongly suggest that nonspecific resistance can be acquired in schistosomiasis.

Although *T. gondii* activates macrophages[12], a factor considered to be largely responsible for the nonspecific protection it affords against other organisms, this protozoan is also a powerful suppressant of B and T lymphocytes[14,20], cells which are necessary for the induction and maintenance of specific immunity. Furthermore, specific acquired resistance in the mouse takes about 3 months to develop, but the protective effects of *T. gondii* and the other nonspecific agents mentioned above are fully manifest within a few days.

With respect to our knowledge of the immunology of schistosomiasis, therefore, it is important not to lump all forms of acquired resistance to infection under the general term immunity, but to determine whether they are specific

or nonspecific. Since both types provide only partial resistance, and their kinetics and mechanisms are different, perhaps their effects may be additive.

Malaria transmission blocked by immunisation with gametes of the malaria parasite

IN view of the limited success of malaria eradication schemes based on concepts of vector control and chemotherapy, serious efforts are being made to investigate the possibility of developing an antimalarial vaccine. So far two classes of vaccine have been under investigation: (1) an anti-sporozoite vaccine designed to prevent malarial infection by blocking the infectivity of sporozoites introduced by mosquito bite[1,2], and (2) vaccines directed against the asexual stages in the blood[3-5]. Although the potential value of such vaccines is unquestionable, their realisation faces technical problems[6]. The latest proposition is to induce immunity against the parasite stages which infect the mosquito and by so doing prevent transmission of the disease by the vector. Gwadz has shown that the infectivity of malarious chickens to mosquitoes can be reduced greatly by prior vaccination with formalin-treated or X-irradiated blood infected with the malaria parasite *P. gallinaceum*[7]. The number of oocysts (the stage of the parasite developing on the wall of the mosquito gut) in mosquitoes fed on vaccinated chickens was reduced by 95–98% below that recorded in mosquitoes fed unvaccinated birds. To achieve this reduction, chickens were given three weekly intravenous inoculations of a total of 4.5 ml of formalin-treated or irradiated blood. Using the same schedule, but with partially purified gametes of the malaria parasite, we have now reduced the infectivity of malarious chickens to mosquitoes at least 99.9% below control levels. To achieve
Fig. 1 The material in the 18,000g pellet (see text) used for vaccinating chickens. The preparation has been fixed and stained with Geimsa for the purposes of illustration. m, Male gamete; f, female gamete; rb, residual body of male gametocyte (precursor cell of male gametes) after release of gametes; pbc, parasitised red blood cell; mz, merozoites (mature asexual cells ready to invade red blood cells); n, nucleus of red blood cell within red cell ghost membrane; ln, lysed nucleus of red blood cell; wbc, white blood cell.

this reduction we had to use a minimum of 0.1 μl of packed cellular material.

We used free gametes for the following reasons. To establish a malarial infection in the mosquito after a blood meal, male and female gametes of the parasite must undergo fertilisation in the lumen of the mosquito midgut. We predicted that this usually rapid process might be blocked by antibodies directed against one or both types of gamete. In the ordinary course of events the vertebrate host is apparently never exposed to the free gametes, which are released in malarious blood only in the gut of the mosquito or on exposure to the atmosphere. It seemed reasonable to assume, therefore, that in natural conditions transmission proceeds in the absence of significant immunity against these stages in the life cycle of the parasite. By vaccinating with and artificially inducing immunity against the free gamete we hoped to block fertilisation and hence prevent transmission of the malaria parasite to the mosquito.

Blood from chickens with high (40–60%) but increasing parasitaemias of *P. gallinaceum* was drawn from the heart and washed immediately in 50 volumes of suspended animation (SA) medium (0.21% Tris; 0.96% NaCl; 0.2% glucose, adjusted to pH 7.4). Suspension of blood in SA medium facilitates removal of factors interfering with fertilisation and transmission, which may be present in the plasma, while the release of malarial gametes (usually spontaneous on exposure of blood to air) is reversibly suppressed. The

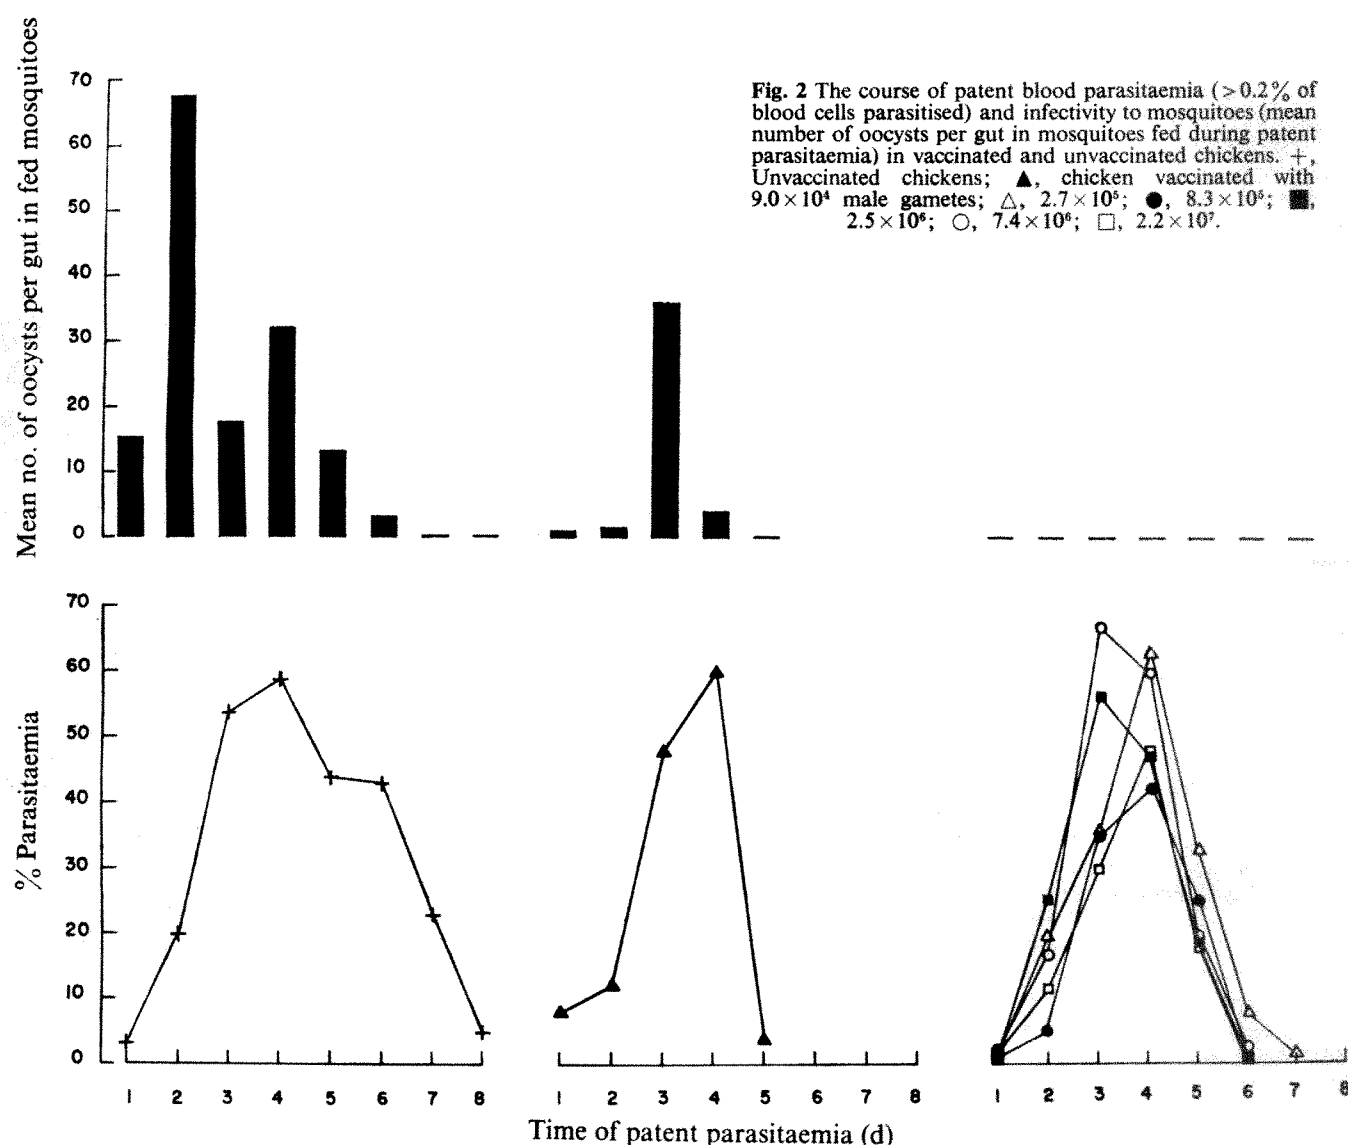
suspension of blood in SA medium was spun at 500g for 5 min and the packed cells were resuspended in a medium that induced the release of the gametes from their precusor cells in the blood (100 volumes of inactivated foetal bovine serum; 20 volumes of 1.46% NaHCO₃; 2.5 volumes of 5% NaCl, and 2.5 volumes of 10% glucose, adjusted to pH 8.0). The cells were incubated for 30 min at room temperature in 2 volumes of the gamete-releasing medium for each volume of packed cells to facilitate complete release of both male and female gametes, the suspension being readjusted to pH 8.0. After centrifugation of the cell suspension for 5 min at 500g the supernatant contained numerous gametes (male and female), some extracellular asexual parasites, red cells, white cells and acellular debris. The supernatant was then spun at 18,000g for 10 min. By visual estimation (comparison of the pellet with measured volumes of methylene blue in identical centrifuge tubes) the amount of material in the 18,000g pellet occupied between one and two thousandths of the packed cell volume of the blood from which it was derived. This was the material used for vaccination (Fig. 1). In view of the heterogeneous nature of the cell and subcellular material in this preparation it was difficult to quantify accurately the relative amounts of gamete and non-gamete material. The yield of male gametes was about 10% of that in the original blood. Male gametes represented about 50% and female gametes about 20% of the cells present. A detailed account of the method of collection of gametes will be published elsewhere.

The 18,000g pellet was resuspended in SA medium and X-irradiated with 20,000 rad. The concentration of male gametes in the suspension was counted using a haemocytometer and the material was diluted in SA medium by threefold steps to give a series of six dilutions (Table 1). Six, 3-week-old, New Hampshire Red chickens were inoculated intravenously with three injections of the irradiated gametes (freshly prepared) in 1.5 ml of SA medium at weekly intervals. The total number of male gametes received by each chicken varied from 9.0×10^4 to 2.2×10^7, representing the yield from 0.05 ml to 11.0 ml of blood at a 40–60% parasitaemia (Table 1). One week after the last inoculation of gametes the vaccinated chickens and one unvaccinated chicken of the same age were challenged with *P. gallinaceum*-infected blood. Peak parasitaemias of 40–60% were achieved in all vaccinated chickens compared with a peak parasitaemia of 58% in the control. A fresh batch of *Aedes aegypti* mosquitoes was fed daily on each chicken throughout its period of patent parasitaemia (defined here as 0.2% or more of blood cells parasitised). Seven days after feeding, 10 mosquitoes from each batch were dissected and their guts were examined for oocysts. The course of patent parasitaemia and infectivity to mosquitoes in experimental and control chickens are shown in Fig. 2. The total number of oocysts produced and the mean number of

Table 1 Oocyst production in mosquitoes fed on vaccinated and unvaccinated chickens

Total immunising dose of male gametes	Volume of parasitised blood from which the gametes were prepared (ml)	Mean no. of oocysts per mosquito gut during the period of patent blood infection	Total no. of oocysts produced throughout the course of infection by feeding 10 mosquitoes per d
Unvaccinated	—	25.2	2,267
9.0×10^4	0.05	8.2	411
2.7×10^5	0.16	0.00	0
8.3×10^5	0.47	0.01	1
2.5×10^6	1.4	0.00	0
7.4×10^6	3.8	0.01	1
2.2×10^7	11.0	0.00	0

Each chicken was vaccinated intravenously at three weekly intervals, the same amount of X-irradiated gamete containing material being inoculated each week. The total amount received by each chicken is indicated in terms of the number of male gametes in the three inocula and the volume of parasitised blood from which the preparations were derived. A single unvaccinated chicken was used as a control. After challenge with live parasites a fresh batch of mosquitoes was fed daily on each chicken during the course of patent blood parasitaemia (>0.2% of blood cells parasitised). Seven days after feeding ten mosquitoes from each batch were dissected and the oocysts on each mosquito midgut were counted.

Fig. 2 The course of patent blood parasitaemia ($>0.2\%$ of blood cells parasitised) and infectivity to mosquitoes (mean number of oocysts per gut in mosquitoes fed during patent parasitaemia) in vaccinated and unvaccinated chickens. $+$, Unvaccinated chickens; ▲, chicken vaccinated with 9.0×10^4 male gametes; △, 2.7×10^5; ●, 8.3×10^5; ■, 2.5×10^6; ○, 7.4×10^6; □, 2.2×10^7.


oocysts per mosquito over the total period of patent infection in each chicken is shown in Table 1.

In a normal infection of *P. gallinaceum* in the chicken the total number of oocysts produced by feeding 10 *A. aegypti* per day throughout the course of infection lies in the range of 2,000–4,000. In our experiment the mosquitoes fed on the unvaccinated chicken yielded more than 2,000 oocysts, representing an average of about 25 oocysts per mosquito during the period of transmission by mosquitoes. By contrast, all but the chicken vaccinated with the fewest gametes were almost totally uninfective to mosquitoes throughout their period of patent infection, oocyst counts being reduced by 99.9–100%. Even for the chicken vaccinated with the fewest number of gametes (9×10^4 gametes equivalent to the yield of 0.05 ml of blood) infectivity, as measured by oocyst production, was reduced by 80% below that of the control. Similar results have been obtained using comparatively highly purified preparations of female gametes as a vaccine and with highly purified male gametes.

Oocyst counts in infected anophelene mosquitoes in areas of holoendemic human malaria are generally less than 10 per gut[8]. In principle the level of suppression of oocyst production achieved in our study should lead to considerable reductions in the infectivity of vectors of human malaria if the same response to gamete immunisation could be reproduced successfully in exposed human populations.

We have demonstrated that a transmission-blocking vaccine based on malarial gametes is easily prepared, uncomplicated in administration (effective without adjuvants) and highly potent in the *P. gallinaceum*–chicken system. But as in the case of other forms of antimalarial vaccines tested with animal systems the translation of a gamete-based vaccine into a realistic measure for combating human malaria faces formidable problems. Not only must the effectiveness of a gamete vaccine be demonstrated for human malarias, but the means of producing large quantities of suitable material must be found. Nevertheless, if satisfactory progress is made in these areas we believe that a vaccine based on the free gametes of the malaria parasite may have considerable significance for the prospects of malaria control or eradication.

The concepts arising from this study may have relevance beyond their application to malaria. In most vector-borne protozoal or helminthic diseases (for example, malaria, babesiosis, trypanosomiasis, lieshmaniasis and filariasis) the disease organisms undergo marked biological transformations after their entry into the vector. It is possible that in some instances vaccination of the host with parasite material from the earliest stages of transformation in the vector may reduce transmission of the disease.

Induction of autoantibodies to red blood cells by polyclonal B-cell activators

THE ability to distinguish self from non-self is a fundamental property of the lymphoid system. One hypothesis for immunocyte triggering[1] proposes that the encounter between antigen and immunoglobulin receptors results in irreversible tolerance, whereas activation requires additional signals, thus ensuring that tolerance to self-antigens will always be the first and easiest event to achieve. An alternative view is that the self–non-self discrimination is carried out by T cells[2,3], whereas B cells could never be made tolerant to thymus-dependent antigens, including autologous antigens, because these antigens cannot deliver any signal to B cells by interacting with the Ig or any other B-cell receptor[4,5]. Experimental support for this notion has been obtained by the demonstration that tolerance to autologous antigens can be broken by the injection of cross-reacting antigens[6] and that there are antigen-binding human B cells able to bind human thyroglobulin[3]. To distinguish between the two hypotheses, it is necessary to determine whether tolerance to self-antigens exists at the B-cell level. This can be done by treating lymphocytes with polyclonal B-cell activators (PBA) and studying antibody formation against autoantigens, for PBA are competent to active B cells of any specificity and thus to reveal the total V gene repertoire of the B cells. We have activated bovine spleen cells in culture with PBA (lipopolysaccharide (LPS) from *Escherichia coli* 055 : B5 and purified protein derivative (PPD) of tuberculin) and studied the number of plaque-forming cells (PFC) appearing against autologous red cells and heterologous red cells coated with the hapten NNP. In all experiments, the spleen cells and the red cells were derived from the same animal. We found that PBA-activated bovine lymphocytes synthesised autoantibodies agains their own red cells.

As shown in Fig. 1, which represents the results from three cows, there was a response measured as thymidine incorporation to different concentrations of LPS, although to a lesser extent than with mouse spleen cells. But LPS induced activation, as determined by an increased thymidine incorporation, was highly significant, being three to six times the background values.

To study induction of autoantibody synthesis, bovine spleen cells were cultured in serum-free medium and stimulated with different concentrations of LPS and in some experiments also with PPD. After 2 d PFC against autologous red cells and hapten (NNP)-coated sheep red cells were counted. Bovine lymphocytes were used because bovine red cells can be used in the plaque assay[7]. As Fig. 2 and

Table 1 show, antibodies were always induced to NNP-coated sheep red cells although there were fewer PFC than expected from mouse experiments. There was, however, an analogous increase of the number of PFC against untreated autologous red cells. There were usually fewer PFC against autologous cells than against NNP–SRC, but the two showed the same increase over background and the same dose–response curve.

Thus, the polyclonal B-cell activators LPS and PPD could both induce the formation of autoantibodies by bovine spleen cells. These substances also induced thymidine uptake and plaque formation against NNP-coated sheep red cells.

It seemed possible that LPS and PPD would coat the red cells and that the PFC actually detected activity against these added foreign materials. But this possibility can be excluded on the basis of previous experiments[8], because the concentrations of PBA used here were such that antibody formation against the PBA was completely inactivated, whereas polyclonal antibody synthesis was induced. Thus there must be resting B lymphocytes in bovine spleen cells that can be activated, by the addition of PBA, to synthesise antibodies able to lyse their own red cells.

These findings have far reaching implications for an understanding of the mechanism of self–non-self discrimination. They indicate that B cells are not normally tolerant to their own thymus-dependent self constituents. This agrees with findings on experimentally induced tolerance to a thymus-dependent protein antigen in mice, where completely tolerant animals had a normal complement of B lymphocytes able to produce antibodies against the tolerogen after activation by LPS (refs 9, 10).

The findings also have implications for an understanding of the mechanism of B-lymphocyte activation. According to the two-signal concept[1], signal one occurs after interaction between the antigen and the Ig receptor and results in an irreversible state of immunological tolerance. Only the simultaneous addition of both signals results in lymphocyte activation, whereas signal two alone has no effect. The alternative hypothesis suggests that only one non-specific signal activates the B lymphocytes[5]. This signal is not delivered by the Ig receptors, but rather by non-clonally distributed receptors for PBA, since B lympho-

Fig. 1 Induction of DNA synthesis with different concentrations of LPS in bovine lymphocytes in serum-free microcultures using 5×10^5 cells per well in 0.2 ml of Eagle's minimum essential medium in Earle's solution containing amino acids and antibiotics as described by Mishell and Dutton[9,11]. The cultures were incubated at 37 °C as described before[12], and after 1–2 d each well received 1 µCi of ^{3}H-thymidine. The cultures were then collected 24 h later on glass fibre filters in a multiple harvester. The filters were dried, scintillation fluid was added and they were counted in a liquid scintillation counter. The figures below the bars denote the cow number in Table 1.
Fig. 2 Induction of autologous PFC in serum-free cultures with bovine lymphocytes stimulated with different concentrations of LPS and PPD. The numbers below the bars indicate cow number. Values are expressed as PFC per 10⁶ lymphocytes. 1×10^7–2×10^7 spleen cells were cultured in 1 ml of medium in 3-cm plastic Petri dishes set up in triplicate The cultures were incubated on a rocking platform for 2 d and thereafter the cells were assayed in a modified[13] agar plaque assay[14] using untreated autologous red cells or haptenated (NNP) sheep red cells. Haptenation was carried out as before[13].

cytes from bovine spleens must necessarily have been in continuous contact with their own red cells, and in spite of this did not become irreversibly tolerant. The results suggest that interaction between Ig receptors and self antigens does not give a tolerogenic signal.

It has been pointed out that the self–non-self discrimination might be executed entirely at the T-cell level[2-5]. This is usually sufficient to maintain a state of self–non-self discrimination, because the autologous antigens are thymus dependent and thereby require cooperation between T and B cells for induction of an immune response. Since the self-reacting T cells would be absent, induction would not usually occur. Induction could be achieved, however, if the cells are given the relevant triggering stimulus delivered by different polyclonal B-cell activators as shown in this experimental system. This would usually occur as a consequence of exposure to PBA material, as happens in infections with organisms having or releasing PBA material. This is probably the reason for autoantibody formation in chronic infectious diseases such as mycoplasma infections,

leprosy, malaria and so on, where it has been shown clearly that the infectious organisms have polyclonal B-cell activating properties.

Genetic control of the response of chicken leukocytes to a T-cell mitogen

THE way in which mitogens stimulate lymphocytes to divide in culture is not known. Some mitogens (for example, bacterial lipopolysaccharides) stimulate immunoglobulin-bearing lymphocytes to divide and secrete antibodies; others, such as concavanalin A (con A) or phytohaemagglutinin (PHA), stimulate thymus-derived cells (T cells) to proliferate[1,2]. An analysis of the mechanism of action of these mitogens may be helpful in deciding how specific lymphocytes respond to

Table 1 Induction of PFC against NNP-coupled and autologous red blood cells by LPS after 4 d in serum-free cultures containing 2×10^7 cells each

	Autologous	2	4	14	8
7	NNP-SRC	7	32	27	
	Autologous	6	24	31	

Bovine spleens were collected immediately after slaughter and the interior part was cut out. Blood samples were drawn simultaneously from the same animal.

Fig. 1 Responses of peripheral blood leukocytes from CB (·--·), WA (——), and (CB × WA)F₁ (--) birds to various doses of con A. Mean and range of responses of four birds from each strain are given for each dose The response of a single bird is measured as the mean of ³H-thymidine uptake in triplicate 96-h microcultures, each culture containing 1.5×10^6 leukocytes in 200 µl RPMI 1640 medium supplemented with penicillin (100 IU ml⁻¹), streptomycin (100 µg ml⁻¹), and glutamine (2 mM) plus the specified dose of con A (Miles, Kankakee, Illinois). Cultures were set up in flat-bottomed wells of Falcon 3040 plates and collected as described previously[6] 16 h after addition of ³H-thymidine (2 µCi in 50 µl culture medium; specific activity 2 Ci mmol⁻¹) to each culture.

antigen. We report here a case of genetic control of the ability of leukocytes to respond to a T-cell mitogen; lymphocytes from certain inbred chicken lines give a high proliferative response to con A, whereas those of other lines give a low response. The chicken provides a suitable model for studying such responses, in particular because it is easy to culture avian peripheral blood leukocytes and thus compare the results of mitogen stimulation directly with those obtained using human peripheral blood cells.

The CB and WA chicken lines used in these experiments are highly inbred[3,4]. Peripheral blood leukocytes, prepared as described by Greaves et al.[5], were cultured in the presence of varying doses of con A and PHA in microculture trays; after a fixed period (usually 3 d) ^{3}H-thymidine was added to the cultures and after a further 16 h, the cells were collected and uptake of radioactivity (presumed to reflect DNA synthesis) was determined as described previously.[6].

Figure 1 shows the responses of leukocytes from adult (9–36-month-old) birds of the CB and WA strains, and of $(CB \times WA)F_1$ hybrid birds, to various doses of con A. The responses of WA and F_1 birds are similar and are at least fivefold higher than the response of CB birds at all doses of con A except the (possibly toxic) highest tested. The responses were measured after 96 h, but, as Fig. 2 shows (for a selected dose of con A), the difference between the two strains can be seen throughout the response (that is, from 2–4 d).

Figure 2 also shows that leukocytes of the two strains respond equally well, or almost so, to a second T-cell mitogen, PHA; although only shown for a particular dose of PHA, this is true for a wide range of PHA concentrations. This fact, as well as providing a useful control for the survival of the leukocytes in culture, shows that the low response of the CB strain to con A is not caused by a defect in the ability of CB leukocytes to proliferate in culture (indeed, as shown previously, the response of CB leukocytes in a mixed leukocyte reaction is as good, or almost as good, as that of WA leukocytes[6]).

An analysis of the responses to con A of leukocytes from $(CB \times WA)F_2$ and $CB \times (CB \times WA)$ backcross birds is given in Fig. 3. Of 31 F_2 birds tested, 22 were high and 9 low responders. Of 8 backcross birds, 5 were high and 3 low responders. Most, including all the low responders, have been tested at least twice

Fig. 3 Genetic control of the response of chicken peripheral blood leukocytes to con A. The responses of leukocytes from individual CB ($\bigcirc$), WA ($\bullet$) and (CB × WA)F$_2$ ($\blacksquare$) or CB × (CB × WA)F$_1$ backcross ($\blacksquare$) birds were measured after 96 h in culture, as described in the legend to Fig. 1, in three experiments. In the first (a), the responses of CB, WA and 14 randomly chosen (CB × WA)F$_2$ hens were measured; of the F$_2$ birds, 3 are low, and 11 high responders. In the second experiment (b), the responses of CB, WA and 14 selected F$_2$ birds (hens $\female$ and cocks $\male$) were measured; of the F$_2$ birds, 7 are high and 7 low responders. The birds were selected as high and low responders on the basis of previous experiments. In the third experiment (c), the responses of CB, WA, and 8 randomly chosen CB × (CB × WA) backcross birds were measured; of the backcross birds, 5 are high and 3 low responders. In each experiment, the responses to various doses of con A were measured; the values given are responses to the dose giving the optimum distinction between high and low responders (2.5, 2.5 and 0.25 μg ml^{-1} of con A, respectively).

with consistent results. These findings indicate that a single, dominant gene controls the ability of peripheral blood leukocytes from the two strains to respond to con A in culture. We have provisionally called this locus *Mr*1 (mitogen response 1) and its alleles *Mr*1-*hi* (WA) and *Mr*1-*lo* (CB).

Table 1 gives the results of tests for genetic linkage of the *Mr*1 locus to the major histocompatibility (B) complex (which actually includes at least three closely linked loci[7–9]), and to the linked G1 and M1 immunoglobulin allotype loci[10,11].

Fig. 2 Time course of responses of peripheral blood leukocytes from CB and WA birds to con A (2.5 μg ml^{-1}) and PHA (1:100 diluted from PHA-M (Difco) stock). Cultures were set up in triplicate for each time point and pulsed for 16 hr with ^{3}H-thymidine before being collected at the specified times, as described in the legend to Fig. 1. The source of CB (or WA) cells was a pool of leukocytes prepared from three CB (or WA) birds. Each point represents the mean of the triplicate values. Vertical bars represent the range of responses of three individual CB ([) and WA (]) birds to PHA (1:100 dilution), measured after 96 h (in a separate experiment, in identical conditions).

Table 1 An autosomal locus, not part of the major histocompatibility or immunoglobulin gene complexes, controls the response of chicken peripheral blood leukocytes to con A

	High	Low	Total
	21 (22.5)	9 (7.5)	30
Bl/1	8 (9.0)	4 (3.0)	12
Bl/9	9 (9.7)	4 (3.3)	13
B9/9	4 (3.7)	1 (1.3)	5
Gla/a	5 (4.5)	1 (1.5)	6
Gla/d	8 (10.5)	6 (3.5)	14
Gld/d	8 (7.5)	2 (2.5)	10
$\male$	10 (12)	6 (4)	16
$\female$	11 (10.5)	3 (3.5)	14

Phenotypes of 30 randomly chosen chickens derived from an F$_2$ cross between the inbred lines CB and WA. The B locus antigens (Bl or 9)[3,4], immunoglobulin G allotypes (Gla or d, which in this cross are associated with the immunoglobulin M allotypes Mla or Mlc respectively)[10,11] and sex of each bird were determined, as well as the reactivity (high or low) of its peripheral blood leukocytes towards con A. Numbers of birds of each phenotype are given, together with (in parentheses) expected numbers if there is no genetic linkage between loci controlling response to con A and the other listed factors. Phenotypes of the parental lines are: CB, Bl/1, Gla/a; WA, B9/9, Gld/d.

The *Mr*1 locus is not linked to these loci, nor is it sex linked or sex limited (Fig. 2). Tests for linkage of the *Mr*1 locus to loci controlling a serum albumin polymorphism[12], feather colour[13], and the C and E blood group antigens[14] have also proved negative (J.R.L.P., V.M., and K. Hála, unpublished).

A single-gene effect on the ability of leukocytes to respond to con A could have a number of explanations, of which some may be tested directly. For example, the WA, but not the CB, strain may have a lymphocyte surface receptor which has a high affinity for con A, and which, on reaction with con A, triggers the cell to divide. An alternative, but equally likely, explanation is that a subpopulation of leukocytes (presumably of T lymphocytes[2]), whose size differs in the two strains, responds to con A. The *Mr*1 marker may prove useful in identifying the putative receptor, or T-cell subpopulation, involved in the response.

Other cases of genetic difference in the ability to respond to mitogens have been described: lymphocytes from mice of the C3H/HeJ strain do not respond to lipopolysaccharides, whereas cells from other mouse strains respond well; the response is controlled by a single non-H–2-linked and non-Ig allotype-linked gene[15]. Small differences, shown to be genetic, in the ability of different mouse and rat strains to respond to the T-cell mitogens con A and PHA have been described[16,17]; this differs from our results in that low responders to con A were also low responders to PHA, suggesting that polymorphism of a specific con A receptor is not an explanation for the observed differences. No genetic differences in the ability to respond to mitogens have been established in human populations, but that such differences may exist is clearly a point to consider when the results of mitogen stimulation assays of human T-cell function are being assessed.

Presence of HLA-D
determinants on human macrophages

When lymphocytes from two genetically dissimilar individuals are cultured *in vitro*, blast transformation and increased DNA synthesis occur in some of them; this is the mixed lymphocyte culture (MLC) interaction[1,2]. In man, the MLC-activating determinants seem to be coded for by the genes of the HLA chromosome region, of which the HLA-D determinants seem to induce the strongest proliferation. HLA-D determinants are expressed on B cells[3], skin cells[4] and sperm[5]. Human macrophages can also activate allogeneic lymphocytes *in vitro* as detected in the

mixed lymphocyte macrophage culture (MLMC) interaction[6,7]. The stimulating activity of the macrophages seems to be much greater than that of peripheral blood lymphocytes. Human Ia-like antigens (B-cell antigens) are strongly expressed on macrophages[8,9]. In the mouse, the lymphocyte-activating determinants of the *M* locus as well as those of the *H–2* loci are also expressed on macrophages[10]. We now present evidence that the lymphocyte-activating determinants on human macrophages are also coded for by the *HLA-D* locus and that an antiserum against HLA-Dw2 (Ia-equivalent) or closely associated determinants can inhibit specifically the stimulatory properties of macrophages from Dw2-positive donors.

Leukocytes were separated from human peripheral blood by Ficoll–Isopaque flotation. Relatively pure macrophage populations were obtained by incubating the isolated leukocytes in plastic flasks for 8 h. The non-adherent cells, mainly lymphocytes, were decanted by repeated washing and the adherent cells were incubated for a further 7–8 d, after which the peripheral blood monocytes had matured into macrophages and the granulocytes had died out. The macrophages were collected by scraping the flask sides with a rubber policeman in calcium-free medium containing EDTA, and the cells were washed out in the same medium. The MLMC technique is described in the legend to Fig. 1. Stimulating macrophages were obtained from individuals known to be homozygous for a particular HLA-D determinant and used as typing cells against a panel of lymphocytes previously typed to be HLA-D heterozygous. In addition, macrophages were isolated from HLA-D heterozygotes and used as control stimulators for determination of the relative response. The anti-HLA-Dw2-associated antibody serum SφW was produced by planned immunisation of HLA-A, HLA-B identical volunteers[11].

The pooled results from five experiments with macrophages from donors homozygous for either the Dw2 or Dw3 determinants are shown in Fig. 1. Macrophages homozygous for a particular HLA-D determinant stimulated rela-

Fig. 1 HLA-D typing results obtained with macrophages from HLA-D homozygous donors (Dw2 and Dw3). Responding lymphocytes were separated from donors previously typed to be Dw2 positive (○) or Dw2 negative (■); Dw3 positive (▲) or Dw3 negative (●). Responding cells (50×10^3) were mixed in combination with macrophages (10×10^3) in 0.2 ml of medium RPMI 1640 containing antibiotics and 20% human AB serum in the wells of microtitre plates. The plates were incubated for 5 d and collected after an 18-h pulse of ^{3}H-thymidine. The results are expressed in relative response (RR) calculated from the formula:

$$RR = 100 \times \frac{\text{c.p.m. MLMC (homo.macrophages)} - \text{c.p.m. autologous culture}}{\text{c.p.m. MLMC (heteroz.macrophages)} - \text{c.p.m. autologous culture}}$$

The heterozygous macrophage control donors were always Dw2 or Dw3 negative respectively. Pooled data from five experiments.
tively weakly (RR < 40%) lymphocytes from heterozygous donors previously typed to possess the HLA-D determinant shared with the macrophage donor. This was the case for both the Dw2 and Dw3 determinants in all combinations tested (Fig. 1). Macrophages did, however, stimulate lymphocytes not sharing the particular HLA-D determinant to a degree comparable with that observed with stimulation by heterozygous macrophages (RR > 70%), where a known two-haplotype incompatibility existed. A clear bimodality of the relative response distributions for the various responding cell donors, similar to that observed using homozygous lymphocytes as stimulating cells in typing MLC tests was observed for the macrophage stimulation for both specificities tested. In no experiment was it possible to demonstrate stimulation of lymphocytes by autologous macrophages, nor to demonstrate increased macrophage proliferation by culturing these cells in combination with mitomycin-treated allogeneic lymphocytes.

It seems therefore that the HLA-D determinants are found in the cell membrane of both lymphocytes and macrophages. This would account for the fact that macrophages from HLA-D homozygous donors failed to, or only feebly stimulated heterozygous lymphocytes sharing an HLA-D determinant. In other words, the HLA-D typing results obtained with homozygous macrophages or lymphocytes were completely congruent, and so a macrophage-specific differentiation antigen cannot be responsible for the positive response observed in MLMCs. In addition, little stimulation was observed in MLMCs between unrelated individuals typed to be HLA-D identical (unpublished observations).

We investigated whether antiserum shown specifically to inhibit the stimulating capacity of lymphocytes possessing the Dw2 determinant could also inhibit specifically the stimulating capacity of macrophages from Dw2-positive donors. This antiserum has been found to inhibit the stimulating capacity of lymphocytes possessing the Dw2 determinant, while inhibiting the responding cells to a much lesser degree[11]. MLMCs were established in medium supplemented with either 20% normal human AB serum or a 1 : 1 mixture of the antiserum in normal AB serum. The antiserum had a significant inhibitory effect (> 50% reduction compared with controls) on all the stimulating macrophages possessing the Dw2 determinant (Fig. 2), but inhibited

Dw2-negative cells only slightly. The inhibiting effect of macrophages from individuals shown to be homozygous for the Dw2 specificity was particularly pronounced (Fig. 2). The stimulating properties of homozygous cells of other specificities however, were not inhibited significantly. The results of these inhibition experiments support the assumption that identical or closely linked stimulating structures (HLA-D) exist on macrophages as well as on lymphocytes.

The macrophage has a well known helper function in MLC, and cultures devoid of such cells do not give a positive response[12]. No specificity for this function has been demonstrated in human MLC, and the necessary macrophages can be either autologous or allogeneic to the responding cell. This helper function can be replaced by cell-free supernatants derived from adherent cells[14], but not by mercaptoethanol[7]. Macrophages are also important in the presentation of mitogens and soluble antigens to T cells[15,16], and in the mouse effective cooperation requires identity between the macrophages and the T cells at the H-2 I region[17], and therefore possibly the Ia determinants. It has been suggested that alteration of Ia determinants by antigen is the stimulatory signal in lymphocyte activation[18]. Our finding that the HLA-D determinants are present on human macrophages may indicate a similar function for HLA-D in man. The ability of macrophages to stimulate allogeneic lymphocytes, however, is probably a result of direct interaction between the stimulating determinants in the macrophage cell membrane and the responding lymphocytes, and not to a helper function *per se*, although this ability may be part of a more general T-cell activation mechanism.

Fig. 2 The inhibiting effect of an anti-HLA-Dw2-associated antiserum on macrophage stimulation. Open columns, c.p.m. of the cultures in 20% normal serum-supplemented medium; stippled columns, results in medium supplemented with 10% normal serum plus 10% antiserum. *a*, Responder (Dw3/oh) was the antiserum producer; *b*, an unrelated donor (Dw5/Dw6), not possessing the Dw2 determinant. The HLA-D typing data of the macrophage donors are shown. The results are the median and the range of triplicate cultures in c.p.m. Autologous responses have been subtracted.

Origin of immunoglobulin–albumin complexes

THE propensity of human IgA and IgM monoclonal proteins to complex to endogenous serum proteins, such as albumin and α_1 antitrypsin (α_1AT), has been previously established[1-3]. When complexes of IgA-albumin and IgA-α_1 antitrypsin are isolated, albumin and α_1AT are found on separate polymeric IgA molecules and not on monomeric IgA[3]. Another polypeptide chain, J chain, has also been shown to exist in polymeric IgA and IgM (refs 4 and 5) but not monomeric immunoglobulin. Furthermore, J chain is synthesised within IgA and IgM mouse plasma cells[6]. Therefore, it is important to determine

whether albumin is complexed to immunoglobulin as a step in intracellular biosynthesis or whether it is incorporated as a post-secretory event. We report here that IgG and IgA mouse plasmacytoma cells synthesise and secrete albumin complexed to immunoglobulin.

The synthesis of mouse immunoglobulin and albumin was studied using the incorporation of ^{14}C-leucine into plasmacytoma cells of the IgG (LPC-1), IgA (MOPC-315A, TEPC-15, HOPC-8) and IgM (MOPC-104E) class as described pre-

viously[7,8]. All tumour lines were obtained from Litter Biometrics and maintained by serial subcutaneous passage in BALB/c mice. Their identity was confirmed by direct immunofluorescence and by light microscopy. After detergent lysis with 0.5% Nonidet P-40 at 4 °C for 15 min, protein from cell lysates and secretions was extracted using monospecific antiserum to mouse proteins above equivalence. The antisera to mouse IgG and IgA was subjected to affinity chromatography using a mouse albumin immunoadsorbent column. The anti-albumin antiserum was adsorbed using a mouse IgG immunoadsorbent column and shown not to precipitate radioiodinated mouse IgG double antibody precipitation. As a control for nonspecific precipitation, normal rabbit serum and an excess of goat anti-rabbit 7S globulin antiserum was added to an aliquot of all preparations. The immune precipitates were then analysed on sodium dodecyl sulphate (SDS) gels[7].

The results of SDS–acrylamide (5%) electrophoresis of secretions from LPC-1 plasmacytoma cells, collected after 3 h of incubation with ^{14}C-leucine, are shown in Figs 1 and 2. Immunoprecipitation of IgG from these secretions followed by reduction yields two radioactive peaks, corresponding to γ and L chains (Fig. 1a). Complete depletion of IgG from secretions was shown by splitting the supernatant of the IgG precipitate into two fractions and testing aliquots, and reprecipitating with
Fig. 1 SDS–polyacrylamide (5%) gel electrophoresis of reduced and alkylated radioactive, secreted mouse IgG (LPC-1). The LPC-1 cell suspension (15×10^6) was incubated in 3.0 ml of Eagle's medium minus leucine containing 10 μCi of ^{14}C-leucine at 325 mCi mmol^{-1} for 3 h at 37 °C. The cell suspension was chilled to 4 °C and made 0.06 M in iodoacetamide. After removal of the cells by centrifugation the supernatant was adjusted to contain 0.5% (w/v) Nonidet P-40 and dialysed against 0.5% Nonidet P-40 in PBS. The resultant secretion was precipitated in 0.06 M iodoacetamide by the addition above equivalence of a monospecific rabbit antiserum to mouse IgG adsorbed with mouse albumin. The precipitate was removed by centrifugation and the supernatant aliquoted into two fractions and further reacted with either rabbit anti-mouse IgG (200 μl) or rabbit anti-mouse albumin antiserum (200 μl) followed by the appropriate amount of mouse IgG (25 μg) or albumin (25 μg) to ensure complete precipitation. The precipitates were washed and dissolved in 2% sodium dodecyl sulphate (0.1 M iodoacetamide), 0.1 M sodium phosphate, pH 7.0, by heating at 100 °C for 2 min. Reduction was carried out with 0.5 M 2 ME by heating for 2 min at 100 °C and alkylation accomplished with excess iodoacetamide. Samples were electrophoresed in 0.1% SDS. The gels were sliced into 1-mm sections, eluted and counted and plotted with the top of the gel on the left-hand side of the figure. a, Reduced anti-IgG immune precipitate; b, supernatant of a reacted with an excess of either anti-IgG (——) or anti-albumin (- - -) antiserum. Arrows indicate marker proteins run simultaneously on separate gels. γ, Gamma heavy chains; L, light chains.

Fig. 2 SDS–polyacrylamide (5%) electrophoresis of ^{14}C-leucine-labelled LPC-1 cell secretions (3 h) precipitated with rabbit anti-albumin antiserum. Incubation with radioactive leucine and preparation of immune precipitate for SDS electrophoresis was as described in Fig. 1. a, Reduced and alkylated anti-albumin precipitate before (——) and after (- - -) adsorption of antiserum with mouse albumin; b, supernatant of the anti-albumin precipitate in a (——) further reacted with either anti-IgG (——) or anti albumin (- - -) antiserum and analysed after reduction and alkylation. Marker proteins are indicated by arrows.
either an anti-IgG or anti-albumin antiserum (Fig. 1*b*). Similar results were obtained using double antibody precipitation with goat anti-rabbit gamma globulin. When anti-albumin antiserum is used to precipitate LPC-1 secretions, two peaks of radio-activity are again seen after reduction, which correspond to γ and L chains (Fig. 2*a*). This radioactive pattern is eliminated when the anti-albumin antiserum is adsorbed with the use of a mouse albumin immunoadsorbent column before precipitation of the secretion (Fig. 2*a*). A control of mouse serum added to secretions and precipitated with rabbit anti-mouse transferrin antiserum showed no precipitated radioactivity on SDS gels. Finally, the supernatant of the anti-albumin precipitate was totally depleted of radiolabelled albumin, while IgG γ and L chains were still present (Fig. 2*b*).

To demonstrate that anti-albumin antiserum specifically precipitated IgG associated with albumin, the amount of IgG (c.p.m.) in secretions before and after this immuno-precipitation was determined. IgG radioactivity in the secretion was depleted by 30–50%, using an anti-IgG antiserum for quantification. These experiments suggest that the precipitation of IgG by anti-albumin antiserum was due to complex forma-tion between albumin and IgG, although no radioactive peak corresponding to albumin was seen on 5% SDS gels.

Since albumin could be secreted unlabelled by the IgG

Fig. 3 LPC-1 cell secretions externally labelled with [125]I. Secretions were collected after 3 h of incubation as in Fig. 1 and then externally labelled[9,10] with ^{125}I and processed as given in legend to Fig. 1. Anti-IgG (*a*) and anti-albumin (*b*) antisera were used to react with secretions and the immune precipitates were electrophoresed, unreduced, on 5% SDS-polyacrylamide gels. Marker proteins, indicated by arrows, were obtained by radio-iodinating isolated mouse IgG and albumin and precipitating these proteins in the presence of unlabelled secretions with monospecific antiserum. Alb, albumin.

Fraction no.
Fig. 4 Radiolabelled albumin secreted from LPC-1 cells after 5 h of incubation with ^{14}C-leucine. Conditions of incubation and handling of immune precipitates were as in Fig. 1. Secretions were precipitated with anti-albumin antiserum and reduced and alkylated and electrophoresed on 10% SDS-acrylamide gels with appropriate markers as in Fig. 1.

plasma cells, LPC-1 cell secretions were externally labelled[9,10] with ^{125}I and after immunoprecipitation were analysed un-reduced on 5% SDS gels. The anti-IgG precipitate of a 3-h secretion had two radioactive peaks corresponding to albumin and IgG (Fig. 3*a*). Similarly, the anti-albumin precipitate showed two peaks with analogous molecular weights on SDS gels (Fig. 3*b*), although the proportion of albumin to IgG differed from that obtained with antiserum to IgG. No discern-ible peaks were obtained on SDS gels of radioiodinated control secretions precipitated with anti-transferrin antiserum or normal rabbit serum and goat anti-rabbit gamma globulin. Planimetry of the graphs showed that the IgG–albumin complex was composed of 1 mol albumin per mol IgG and approximately 30% of the secreted IgG molecules were complexed to albumin. This accounts for the larger IgG peak seen with the IgG pre-cipitate compared to the albumin precipitate. These experiments demonstrate that albumin is non-covalently bound to IgG and does not dissociate in the detergent, Nonidet P-40, although there is dissociation in SDS. Results obtained with three different IgA plasmacytomas were analogous to the IgG plasmacytoma, that is, albumin was secreted non-covalently bound to IgA. Neither albumin synthesis or secretion was found in IgM plasma cells.

To determine whether the albumin secreted from IgG and IgA plasma cells originated after biosynthesis or was adsorbed to the cell, lysates were examined after 3 h incubation with ^{14}C-leucine. In contrast to secretions, the cell lysates demonstrated a distinct radiolabelled peak for albumin, in addition to IgG, with anti-albumin antiserum. Since IgG and albumin were both radiolabelled in the complex present within the cell, it was pos-sible that longer incubation periods would show ^{14}C-leucine incorporated into secreted albumin. The experiment in Fig. 4 depicts a 5-h LPC-1 secretion precipitated with antiserum to albumin and shows a third peak corresponding to albumin, in addition to γ and L chains. Furthermore, gel filtration of 5-h secretions on Biogel P200 equilibrated in 8 M urea demon-strated a component with a molecular weight of 68,000, anti-genically identical to albumin. Similar experiments in three different IgA plasmacytomas demonstrate biosynthesis of albu-min in these cells.

The complexing of albumin to IgG deserves further comment. Since no additional IgG or albumin is found in the supernatant after IgG is precipitated from secretions, this suggests that all of

the secreted albumin is complexed to IgG. One speculation is that the transport of albumin across certain membranes requires immunoglobulin. Furthermore, the albumin found in the complex is secreted by seniority—the older albumin molecules are secreted before the more newly synthesised (labelled) ones. If these complexes are present in the cell membrane, it is possible that the appearance of the complex in the culture media represents cell membrane turnover rather than direct secretion. The biological significance of the complexed albumin may be in the stabilisation of specific receptors on the cell membrane.

Solitary cells and enzyme exchange in tetraparental mice

I REPORT here studies on tetraparental mice made with a greatly improved histochemical method for the enzyme β-glucuronidase. There were two unexpected findings: first, small clusters and solitary cells were found in many mosaic tissues of the tetraparental mice, and second, there was evidence that enzyme exchange occurs normally among cells.

Tetraparental mice are made by aggregating pairs of eight-cell embryos *in vitro*[1,2], and those I used were made from pairs of inbred strains whose tissues are known to differ in β-glucuronidase activity[3]. Thus the mosaic tissues of the tetraparental mice were composed of two intermingled populations of cells which could be distinguished microscopically in tissue sections stained histochemically for β-glucuronidase as originally demonstrated by Condamine *et al.*[4].

Tetraparental mice (provided by Richard J. Mullen) were prepared from C57BL/6J or BALB/cWt (high glucuronidase) and C3H/HeJ or AKR/J (low glucuronidase) embryos[5]. Postnatal tetraparental mice 4 d, 9 d, 25 d, 10 months and 16 months old were used. Tissues from these mice and from homozygous controls were treated in parallel. Tissue specimens fixed in 4% formaldehyde were prepared for microscopy by a method involving several unusual steps, including incomplete dehydration, embedding in polyethylene glycol 400 distearate wax treated with NH₄HCO₃ and water, and staining of sections in a solution containing gelatin as well as the usual substrates (details in Fig. 1). This procedure permitted staining and demonstration of mosaicism in a much wider range of cell types than is possible with the method of Condamine *et al.*[4]. In many cells the staining was observed throughout the cytoplasm as well as in the lysosomes. This is in accord with findings that β-glucuronidase, which is a lysosomal enzyme, is also present outside the lysosomes[6,7].

In many tissues of tetraparental mice two populations of cells were readily distinguished by differences in staining intensity. The more intensely stained cells, which I shall call G cells, are assumed to be homozygous for *Gus*ᵇ, the wild-type allele for β-glucuronidase, and thus are assumed to arise from the C57BL/6 or BALB/c embryo. The more lightly stained cells, termed g cells, are assumed to be homozygous for *Gus*ʰ, the allele resulting in lower glucuronidase activity[3] and lower thermal stability[8] of the enzyme; these cells are assumed to arise from the C3H or AKR embryo. Those tissues in which cells were not readily separable into two groups on the basis of staining intensity will be discussed later in this report.

The arrangement of G cells and g cells in a wide range of tissues revealed a thorough intermixture of both types, and a fairly widespread occurrence of small clusters of cells in many tissues (Figs 1–3). (I use 'cluster' to refer to a group of cells of one staining type surrounded by cells of the contrasting type.) There was striking variation in the ratio of the number of G cells to g cells as well as in size of clusters from animal to animal, from organ to organ within the same animal, and even from place to place within the same organ. Though large clusters were common, cells in small clusters (those containing fewer than 10 cells as viewed in a single section) made up between roughly 1% and more
Fig. 1 Liver of 10-month-old tetraparental mouse showing mosaicism after staining for β-glucuronidase. About a dozen hepatocytes are intensely stained (G cells); the remaining hepatocytes—about 90% of all hepatocytes in this field—are lightly stained (g cells). (The much smaller, intensely stained cells are Kupffer cells.) Mice were fixed by intracardiac perfusion for 5 min with 4% formaldehyde (from paraformaldehyde) in a 0.15 M sodium phosphate buffer, pH 7.4. The whole mouse was then placed in a water-ice slurry. After 2–3 h, the organs were removed in a cold room at 4 °C and immersed in the same fixative at 0 °C for a total fixation time of 6 h. Specimens were rinsed at 0–4 °C for 2–5 d in several changes of 6% polyvinyl pyrrolidone (molecular weight 10,000) plus 10% sucrose (compare ref. 24), then dehydrated for 1–2 d at 0–4 °C in 98:2 acetone–water (several changes), and finally embedded in wax. Polyester wax (= polyethylene glycol 400 distearate)²⁵ at 40–50 °C was stirred for 3 h with 5% by weight of solid NH₄HCO₃ and filtered. Two millilitres of water at 80–90 °C were added with stirring to 100 ml of melted wax at 40–50 °C. Tissue specimens were embedded in the treated wax after infiltration for 0.5–2 d at 37–40 °C (several changes). Sections cut at 5–20 μm were mounted in a shallow pool of water on slides treated specially²⁶ with Mayer's albumen. After sections had dried for ~1 d, slides were dewaxed in acetone, then allowed to dry twice from 9:1 acetone–water (to promote section adhesion). Slides were stained at 37 °C in a solution of hexazotised pararosanilin, naphthol AS–BI glucuronide, and 5% gelatin (Eastman No. 1099); with gelatin, periods of staining up to 5 h were possible before a change of staining solution was necessary. Apart from the gelatin, the composition of the solution was the same as that described by Hayashi *et al.*²⁷. Because of the enormous range of glucuronidase concentrations, optimum staining time ranged from 20 min for some cell types (for example, tissue macrophages)²⁶ to 25 h for others (for example, retinal neurones). The bar represents 50 μm.
Fig. 2 Thyroid of 16-month-old tetraparental mouse. There are about a dozen G cells and about a dozen g cells in each of the four main follicles. The bar represents 50 µm.

than 20% of the total cell population in many tissues. Small clusters were present in the following tissues of the 16-month-old tetraparental mouse and also in the same tissues of at least one of the three young mice (4, 9, and 25 d old): in the parenchyma of liver, pancreatic islets, exocrine pancreas, mucous and serous part of salivary gland, thyroid, parathyroid, adrenal cortex, seminal vesicle and Harderian gland; in the surface epithelium of salivary ducts, non-glandular stomach (basal layer of epithelium), glandular stomach, pylorus, small intestine, trachea, epididymis, choroid plexus, and ependyma; and in some nerve cell groups in the central nervous system.

The smallest 'clusters' consisted of single cells. The proportion of these cells ranged from a small fraction of a per cent up to a few per cent of the total cell population. Individual cells which seemed to be isolated in two dimensions when viewed in a single section were observed in most tissues listed above. The presence of truly solitary cells (those isolated in three dimensions) was verified by examination of serial sections of liver, salivary gland and duct, small intestine, thyroid, seminal vesicle, epididymis, Harderian gland and choroid plexus. Although small clusters and solitary cells have been noted previously[8], this finding was unexpected: there have been several reports of much larger clusters in mosaic tissues—in the range of 10^4 to 10^6 or more cells per cluster[9-14]. This earlier work was based on methods of tissue analysis too crude for the detection of the small clusters which undoubtedly were present.

The presence of a solitary cell in a mosaic tissue means either that a pair of sister cells have separated after the cell division which produced them or that one member of the pair has died. The solitary cells found in this study may have migrated away from their sister cells at any stage of foetal or postnatal life; my observations provide no evidence on when migration occurred. One can, however, infer that cell migration in the region of large clusters was very slow[15] —no more than a few cell diameters of total migration by the average cell throughout postnatal life.

In the tissues discussed above the G cells and g cells formed two distinct populations readily distinguished by their staining intensities. Unfortunately, as previously mentioned, in some tissues many of the cells were of intermediate staining intensity and could not be assigned to either the G cell or g cell group. These included most of the lymphatic system, most connective tissues and many nerve cell groups in the central nervous system.

The differences in staining intensity between cells of tetraparental mice and cells of the same tissues in homozygous control mice showed some interesting regularities. The G cells of some tissues were stained less intensely in tetraparental mice than in the high-glucuronidase strains (C57BL/6 and BALB/c); this was observed in mucous and duct cells of salivary gland, stomach glandular epithelium, absorptive epithelium of small intestine, colon glandular epithelium, thyroid epithelium, adrenal cortical epithelium, renal tubular epithelium, Harderian gland epithelium, chondrocytes, smooth muscle cells, brown fat cells, some nerve cell bodies in the central nervous system, and Schwann cells (in trigeminal ganglion). Also the g cells of some tissues were stained more intensely in tetraparental mice than in the low-glucuronidase strains (C3H and AKR); this was observed in stomach glandular epithelium, absorptive epithelium of small intestine, colon glandular epithelium, adrenal cortical epithelium, renal tubular epithelium, epididymal epithelium, brown fat cells and choroid plexus.

These observations can be explained most simply by postulating a partial exchange of enzyme between G cells and g cells in tetraparental mice. An alternative explanation is that both the G cells and g cells of tetraparental mice have been influenced by the presence of cells of the opposite type to alter their level of endogenous enzyme. The hypothesis of enzyme exchange is supported by the preliminary finding that some g cells of tetraparental mice contain both Gus^b and Gus^h enzyme[16]. Evidence against the exchange of several non-lysosomal enzymes comes from the failure of attempts to detect hybrid molecules of these enzymes in a wide variety of tissues in tetraparental mice. Since hybrids could not be detected (except in skeletal muscle), the monomers of these enzymes apparently do not move from cell to cell (reviewed in ref. 17).

Change of phenotype by transfer of a substance from cell to cell in a mosaic tissue is a well known phenomenon. In the first recognised instance (described by Sturtevant in 1920; reviewed in ref. 18), the substance transferred between cells and found to be responsible for the observed effect proved to be kynurenine, a metabolite of low molecular weight. The findings reported here may be the first demonstration of exchange of an enzyme between cells in an intact animal.

Intercellular exchange of enzymes, particularly of

Fig. 3 Seminal vesicle of 16-month-old tetraparental mouse. There are two layers of secretory epithelium (simple, low columnar) separated by smooth muscle (almost unstained). One epithelial layer contains only g cells; the other layer, G cells and g cells. The bar represents 50 µm.
lysosomal enzymes, may occur widely in tissues of ordinary animals. A similar suggestion has been made previously on other grounds[19]. Since many enzymes (including β-glucuronidase) are readily detectable in plasma and other extracellular fluids, these enzymes are available to be taken up by cells. Furthermore, the uptake of exogenous lysosomal enzymes administered experimentally is known to occur both in the intact animal[20] and in cell culture[21]; β-glucuronidase is among the enzymes for which this process has been demonstrated[22,23]. Moreover, the incorporated enzyme has been shown in some instances to assume its normal function inside the cells that take it up[20,21]. These observations, together with the findings presented here, support the view that exchange of glucuronidase (and other enzymes) among cells actually occurs as a normal function in a wide range of cell types.

The idea of using β-glucuronidase as a cell marker in tetraparental mice for studies of embryonic development was suggested to me by Richard L. Sidman.

Hairbulb tyrosinase activity in oculocutaneous albinism

HUMAN oculocutaneous albinism (OCA), characterised by hypopigmentation of skin, hair and eyes, represents a heterogeneous group of at least four distinct autosomal recessive disorders[1,2]. Tyrosinase-negative OCA and tyrosinase-positive OCA are the two most common forms and can be separated by genetic and clinical features[1]. Tyrosinase-negative albinos have no obvious pigment in their skin, hair or eyes, and their plucked hairbulbs form no visible pigment after prolonged incubation in L-tyrosine or L-3,4-dihydroxyphenylalanine (L-dopa). In contrast, tyrosinase-positive albinos have variable, albeit minimal, amounts of pigment in their skin, hair and eyes, and their plucked hairbulbs form large amounts of visible pigment after prolonged incubation in L-tyrosine or L-dopa. The two less common forms of OCA are Hermansky–Pudlak syndrome and yellow mutant OCA. The specific defect in each form of OCA is unknown, and analysis of the biochemical steps in the formation of melanin have been hindered by a

lack of methods suitable for human studies. In this report, we describe an assay for quantifying tyrosinase activity in single human hairbulbs and give the results of the application of this technique to human oculocutaneous albinos.

Melanin formation occurs in the melanocytes, specialised cells found in the skin, hair follicle and eye[3–5]. Tyrosinase catalyses the hydroxylation of tyrosine to dopa and the oxidation of dopa to dopaquinone[6]. Dopaquinone then undergoes non-enzymatic oxidation and polymerisation to form melanin. Our assay measures the tyrosine hydroxylase activity of tyrosinase, determined by the rate of formation of ^{3}HOH with the oxidation of L-3,5-^{3}H-tyrosine to L-5-^{3}H dopa, as described by Pomerantz[7].

Anagen (growing) hairbulbs plucked from the scalp were used as the source of enzyme. Hairbulbs contain a local concentration of melanocytes that remain in the bulb when a hair is plucked[8], and animal studies have shown hairbulb tyrosinase to be present only during the anagen phase of the hair cycle[9,10].

The activity of normal hairbulb tyrosinase was tested from
Fig. 1 Mean tyrosine oxidised per 120 min for hairbulbs from normal individuals with different hair colours and from oculocutaneous albinos. For albinos: ■, tyrosinase-negative and ▲, tyrosinase-positive. The overall mean is indicated by a line for blond, brown, black and red hair. Single anagen hairbulbs were identified visually, divided from the shaft at the shaft–sheath junction and incubated in tritiated tyrosine, dopa and Triton X-100. The incubation mixture used was determined to be optimum for single hairbulb tyrosinase quantification after many trials with different buffers, concentrations of substrate and cofactor and incubation volumes. The mixture consisted of L-3,5-^{3}H-tyrosine, 0.2 nmol (1 Ci mmol^{-1}), L-dopa, 0.1 nmol; phosphate buffer, pH 6.8, 6 μmol and Triton X-100, 0.5%, in a total volume of 0.06 ml, and was carried out at 37 °C in a shaking waterbath. Nonspecifically formed ^{3}HOH in the stored L-3,5-^{3}H-tyrosine was eliminated by evaporating the sample of tyrosine to dryness under a stream of nitrogen immediately before use. At 0, 60 and 120 min, a sample of the incubation mixture was placed on a Dowex-50W column equilibrated with 0.1 M citrate. The ^{3}HOH was recovered from the column by washing with 0.8 ml of 0.1 M citrate and counted. The wash removed all tritiated water from the column, with no further activity above background recovered with a second wash. A blank consisting of the incubation mixture with no added hairbulbs was run with each assay. Values for the blank were subtracted from the hairbulb values before determining the amount of tyrosine oxidised. The reaction was linear throughout the 120-min incubation for normally pigmented and tyrosinase-positive albino hairbulbs. Boiled hairbulbs had no activity. Usually six to eight hairbulbs were assayed per subject, with enzyme activity expressed in pmol as the mean tyrosine oxidised per 120 min. The activity in the blanks was equivalent to 0.201 ± 0.152 (mean $\pm$ s.d.) for blond, 0.242 ± 0.089 for brown, 0.312 ± 0.153 for black, 0.255 ± 0.191 for red, 0.163 ± 0.172 for grey and 0.317 ± 0.235 for albino hairbulbs.

forty-two subjects with brown, black, blond, red and grey hair (Fig. 1). All subjects were under the age of 35 except for the three with grey–white hair, and no male was balding. The overall mean for seven subjects with blond hair was 0.821 pmol of tyrosine oxidised per 120 min with a range of 0.134–2.066 pmol per 120 min. Hair colour varied from light white–blond to bright golden blond, but there was no obvious association between degree of 'blondness' and enzyme activity. For thirteen subjects with different shades of medium brown hair a mean of 1.446 pmol of tyrosine was oxidised per 120 min with a range of 0.460–2.267 pmol per 120 min. On repeated testing, hairbulbs from two of the brown-haired subjects oxidised a mean of 1.620 ± 0.312 ($\pm$ s.d.) and 1.660 ± 0.266 pmol of tyrosine per 120 min. Ten subjects with black hair oxidised a mean of 1.881 pmol of tyrosine per 120 min with a range of 0.512–3.162 pmol per 120 min. Two of these subjects were black, and three were Oriental, but there was no association between enzyme activity and racial origin. Hairbulbs from nine subjects with red hair oxidised a mean of 3.596 pmol of tyrosine per 120 min, with a range of 1.352–5.862 pmol per 120 min. The variation was great between these subjects, but there was no obvious association between degree of 'redness' and enzyme activity. Grey–white hairbulbs from three subjects had little or no tyrosinase activity.

Four tyrosinase-negative albinos lacked enzyme activity in their hairbulbs (Fig. 1). Five tyrosinase-positive albinos could be divided according to activity into two groups (Fig. 1). Three had high enzyme activity, oxidising a mean of 4.819, 4.325 and 3.874 pmol of tyrosine per 120 min. These levels are equalled only by normal subjects with red hair. Beard anagen hairbulbs rather than scalp hairbulbs were used from one of the tyrosinase-positive albinos with high activity (4.325 pmol per 120 min) because of the inability to pluck adequate samples of scalp anagen hairbulbs. To verify the use of facial hair, beard hairbulbs from one of the black-haired and two of the brown-haired normal subjects were assayed and were found to have enzyme activity similar to or slightly reduced from the levels found in the same individuals' scalp hairbulbs. Two of the tyrosinase-positive albinos had moderate enzyme activity, oxidising a mean of 1.937 and 1.738 pmol of tyrosine per 120 min. These levels are similar to those for normal subjects with brown and black hair. Clinically, the two with moderate activity differed from those with high activity in that their hair was less pigmented and their visual acuity more reduced. Skin colour was similar in both groups. One of the albinos with moderate activity was 7 months pregnant, but had noticed no changes in skin, hair or eye pigmentation during the pregnancy. Pregnancy affects the hair growth cycle with more hair follicles in anagen[11], but the influence on tyrosinase activity is unknown.

The hydroxylation of tyrosine catalysed by tyrosinase utilises dopa as cofactor, and proceeds very slowly in its absence[6,7]. To show that the hairbulb assay described here is dopa dependent, hairbulbs from a brown-haired subject and from a tyrosinase-positive albino were incubated in different

Table 1 Mean tyrosine oxidised per 120 min for different dopa concentrations in incubation mixture

Dopa concentration (mM)	Mean tyrosine oxidised per 120 min (pmol)	
	Brown	Albino
0	0.000	0.000
1.67×10^{-4}	0.162	0.480
1.67×10^{-3}	1.620	4.325
1.67×10^{-2}	1.883	3.327
1.67×10^{-1}	0.945	—

The albino was a high activity tyrosine-positive albino. The incubation mixture contained 0, 0.01 nmol (1.67×10^{-4} mM), 0.1 nmol (1.67×10^{-3} mM), 1.0 nmol (1.67×10^{-2} mM) or 10 nmol (1.67×10^{-1} mM) of dopa in a total volumn of 0.06 ml. The rest of the assay was as described in the text.

Table 2 Mean tyrosine oxidised per 120 min for hairbulbs from a brown haired subject

Experiment	Mean tyrosine oxidised per 120 min (pmol)
(A) Triton X-100 0.5% (regular assay)	1.620
Triton X-100 2.0%	1.520
Triton X-100 5.0%	0.986
No Triton	0.187
(B) Preincubation in 0.5% Triton	
Hairbulb removed at	
5 min	0.107
10 min	0.721
15 min	1.204
30 min	1.489

For experiment A, hairbulbs were incubated in L-3,5-^{3}H-tyrosine, 0.2 nmol; L-dopa, 0.1 nmol; phosphate buffer, pH 6.8, 2 μmol and Triton X-100, 0–5% in a total volumn of 0.06 ml. For experiment B, hairbulbs were preincubated in 0.03 ml of 0.1 M phosphate buffer, pH 6.8, containing Triton X-100, 0.5%. After the hairbulbs were removed L-3,5-^{3}H-tyrosine 0.2 nmol; and L-dopa, 0.1 nmol were added and the mixture assayed for tyrosinase activity.

concentrations of dopa, as shown in Table 1. When no dopa was added to the incubation mixture there was no oxidation of tyrosine during the 120-min incubation. Dopa concentrations above and below the usual assay concentration gave reduced levels of activity. The assay was clearly dopa dependent. The inhibition at a high dopa concentration was consistent with the action of dopa as a competitive inhibitor of tyrosinase, as shown with mouse and hamster melanoma tyrosinase[6,7].

All the above results were obtained using an incubation mixture containing 0.5% Triton X-100. To test the effect of different detergent concentrations, hairbulbs from a brown-haired subject were assayed in incubation mixtures containing 2%, 5% and no Triton X-100, as shown in Table 2 (experiment A). When no detergent was present, there was little enzyme activity. Triton X-100 (5%) inhibited the activity, and activity with 2% was similar to the regular 0.5%. Triton activation of tyrosinase has been demonstrated, but the exact mechanism of activation is unclear[12]. In the system described here the Triton seemed to release the enzyme from the melanocyte, making it available for assay. This was shown by preincubating brown hairbulbs in 0.5% Triton for 5, 10, 15 and 30 min, after which the hairbulb was removed and the preincubation mixture without hairbulb was assayed for tyrosinase activity by the standard method (Table 2, experiment B). If Triton solubilised the tyrosinase, then the enzyme should have been present in the preincubation solution after the hairbulb had been removed. Hairbulbs preincubated with Triton for 5 min released little enzyme, as shown by an activity of only 0.107 pmol of tyrosine oxidised per 120 min for this preincubation mixture. Preincubation of hairbulbs for 10 and 15 min released progressively more enzyme and preincubation for 30 min released most of the available enzyme as shown by an activity of 1.489 pmol of tyrosine oxidised per 120 min for this pre-incubation mixture. Hairbulbs from this subject oxidised 1.620 pmol, of tyrosine per 120 min in the standard assay.

Three conclusions can be drawn from this study. First, tyrosinase activity can be quantified in single anagen hairbulbs, and varies considerably among normal individuals with different hair colours and among normal individuals with the same hair colour. Although the trend was for more intensely pigmented hair (black and red) to have more hairbulb tyrosinase activity, there was no obvious association between intensity of a specific hair colour and tyrosinase activity. Further studies on the biochemical control of normal hair pigmentation are under way.

Second, tyrosinase-negative albino hairbulbs had no tyrosinase activity by this assay. This is the first quantitative demonstration of absent tyrosinase activity in this form of human OCA and supports the terminology of tyrosinase-negative used by Witkop[1]. The absence of tyrosinase activity

is consistent with the suggestion that this form of OCA is analogous to the c locus (c/c) albino animal[1], for the c locus is thought to control the synthesis of tyrosinase, with c/c animals being deficient in this enzyme[13-15]. Recently, Hearing[12] and Pomerantz and Li[16] have shown that albino mouse eye and skin preparations retain small amounts of tyrosinase activity, 2–3% of that for pigmented eye and skin preparations. Our assay probably would not detect such residual activity in hairbulb preparations. There was definitely no stimulation of activity from tyrosinase-negative albino melanocytes, and there was no evidence for the presence of an inhibitor that could be dissociated from the enzyme by Triton. At present the evidence points to an absence of tyrosinase in tyrosinase-negative OCA.

Third, tyrosinase-positive hairbulbs from tyrosinase-positive albinos contain moderate to large amounts of tyrosinase that can be assayed readily with the system reported here. The defect in this form of OCA does not seem to be an absence of active enzyme, so other mechanisms must be considered. The structure of the tyrosinase-positive melanocyte or melanosome could be altered, but by electron microscopy these appear normal[1]. Substrate availability or transport into the melanocyte could be deficient. The tyrosinase could be structurally abnormal with altered kinetics making it active in non-physiological conditions in vitro but inactive in physiological conditions in vivo. Finally, the activity of tyrosinase could be blocked by an inhibitor, for these have been described for melanoma tyrosinase[17-20]. If an inhibitor is present, the release of tyrosinase from the melanocyte by Triton may also facilitate dissociation of the inhibitor from the enzyme.

There is insufficient information to show which of the above mechanisms is important in the production of tyrosinase-positive OCA. The fact that there seems to be genetic heterogeneity with two types of tyrosinase-positive albinos suggests that more than one mechanism may be active.

Evidence for inhibin-like activity in bovine follicular fluid

THE negative feedback action of testicular steroids on circulating levels of luteinising hormone (LH) is well known. It is less clear how the testis influences follicle-stimulating hormone (FSH). The existence of 'inhibin', a water-soluble testicular product that inhibits the secretion of FSH, was first postulated in 1932 (ref. 1); recently, inhibin activity has been detected in rete testis fluid[2], testicular tissue[3], spermatozoa[4] and seminal plasma[5]. Immunisation of rabbits with the inhibin fraction of bull seminal plasma has produced an antiserum which raised plasma FSH levels when injected into male and female rats[6]. It has been suggested[7] that, in the male, inhibin may be produced by the Sertoli cells of the testis. If this is the case, one wonders if inhibin could also be produced by granulosa cells of the ovary. We have, therefore, looked for the presence of a specific FSH-suppressing agent in ovarian follicular fluid by comparing the effects of fluid and peripheral plasma on the levels of FSH and LH in newly castrated male rats.

A pool of follicular fluid was collected by aspiration from bovine follicles at various stages of the cycle. The concentrations of testosterone and 17β-oestradiol in the follicular fluid, as measured by radioimmunoassay, were 23.5 and 73.1 ng ml^{-1}, respectively; these values agree with reported levels[8]. Bovine plasma, which has a similar protein composition to follicular fluid[9], was obtained from a castrated bull and testosterone and 17β-oestradiol were added to give concentrations of 25 and 75 ng ml^{-1}, respectively, in a low dose pool of plasma, and concentrations of 250 and 750 ng ml^{-1}, respectively, in a high dose pool.

Five groups of adult male rats (body weight 300–400 g), 6–12 animals per group, were castrated under ether anaesthesia. Approximately 1 ml of blood was collected from the cut spermatic artery at the time of castration (sample 1). Four of the groups of animals were injected intraperitoneally immediately after castration with either 0.25 ml bovine plasma, the low or

Fig. 1 Effect of injection of bovine plasma (BP), BP containing a low dose (LD, follicular fluid concentration) or high dose (HD, ten times follicular fluid concentration) of 17β-oestradiol and testosterone, or bovine follicular fluid (FF) on plasma levels of FSH (a) and LH (b) in male rats 24 h after castration. All values are expressed as the percentage of precastration levels (means ± s.e.m., figures indicate numbers of animals).
high dose of steroids in plasma, or follicular fluid; and the animals in the fifth group served as untreated controls. Eight hours after castration a second injection of 0.5 ml of the appropriate fluid was administered subcutaneously. The animals were killed by decapitation 16 h after the second injection and blood was collected from the trunk (sample 2). LH and FSH were measured in samples 1 and 2 by radioimmunoassay[10]. The results of these estimations, expressed as the ratio of the concentration in sample 2 to that in sample 1, $\times 100\%$, are shown in Fig. 1.

The untreated controls and the group treated with bovine plasma did not differ significantly; both showed a two- to three-fold increase in plasma LH and FSH levels after castration. Treatment with the low dose of testosterone and 17β-oestradiol caused a significant decrease in plasma LH and FSH compared with bovine plasma-injected groups ($P < 0.05$ and $P < 0.02$, Student's t test); the high dose of steroids caused an even more marked suppression of both gonadotropins to precastration levels. Injection of follicular fluid caused a much greater suppression of plasma FSH than of plasma LH ($P < 0.01$); FSH being reduced to precastration levels, which were significantly lower ($P < 0.05$) than after treatment with the low dose of steroids. In contrast, plasma LH levels were comparable in the follicular fluid and low dose steroid groups. No significant ($P > 0.05$) differences in pituitary LH or FSH levels were detected between any of the five treatment groups.

To establish the non-steroidal, high molecular weight character of the FSH-suppressing agent in the follicular fluid, a second experiment was carried out. Groups of 6–12 animals were injected with steroid-free follicular fluid after castration as described above. LH and FSH were measured in plasma samples collected at the time of castration and 24 h later (Table 1). The effect on FSH levels of injected follicular fluid after ether extraction, charcoal treatment or ultrafiltration (molecular weight > 10,000) was not different from that of the untreated fluid. The suppression of the increase of LH in castrated rats after injection of untreated follicular fluid was abolished when steroids were removed from the fluid by these three treatments; remaining steroid concentrations were < 1% of the original concentrations in all preparations.

These observations suggest that bovine follicular fluid contains inhibin-like activity, which specifically suppresses FSH and cannot be ascribed to steroids, present in the fluid. The active compound has a molecular weight of over 10,000.

Table 1 Effect of injection of steroid-free bovine follicular fluid on plasma levels of LH and FSH in male rats 24 h after castration

Treatment*	n†	FSH	LH
None	12	215±45	302±72
Follicular fluid (FF)	12	99±23‡	160±89‡
FF, ether extracted	6	104±42‡	219±78
FF, charcoal treated	6	99±24‡	294±64
FF (molecular weight > 10,000)	6	90±30‡	274±189
FF (10,000 > molecular weight > 1,000)	6	172±69	247±127

All results are given as the percentage of precastration levels in the same animals (means ±s.d.). Actual levels of FSH and LH at the time of castration were 366±90 (s.d.) ng ml^{-1} NIAMDD rat FSH RP-1 ($n = 48$) and 55.6±22.9 (s.d.) ng ml^{-1} NIAMDD rat LH RP-1 ($n = 48$), respectively.
*FF, Ether extracted: follicular fluid extracted six times with 1.5 volume of ether. FF, Charcoal treated: follicular fluid stirred with charcoal (1 mg ml^{-1}) for 30 min at room temperature and subsequently centrifuged at 12,000g for 30 min. FF (molecular weight > 10,000): follicular fluid diluted to 10 times its original volume with distilled water and subsequently reduced to its original volume by ultrafiltration (Amicon Diaflo PM 10, cutoff point at molecular weight of 10,000). FF (10,000 > molecular weight > 1,000): the volume of the ultrafiltrate of first filtration was reduced to 0.9 times the original volume by ultrafiltration (Amicon Diaflo UM, cutoff point at molecular weight of 1,000).
†Number of animals.
‡Significantly different from untreated controls (Student's t test, $P < 0.05$).

Other indirect evidence, based on the inhibition of follicular development in immature mice injected with bovine follicular fluid[11], leads to a similar conclusion. Since it is unlikely that this substance could be produced by the one oocyte in the follicle[12], the granulosa cells are a more likely source.

It would be attractive to suppose that inhibin might act at the pituitary level, altering the ratio of FSH and LH secreted in response to releasing hormone. This might explain the changing FSH–LH ratio associated with puberty in both the male and female[13] and would give a new dimension to our understanding of the gonadal feedback control of pituitary gonadotropin secretion.

Prostaglandin mediation of collagenase-induced bone resorption

PATHOLOGICAL bone breakdown may be stimulated by some tissues proximal to bone and the release of collagenase by them may be one cause of this lysis. Inflamed gingivae, for example, have been shown to lyse collagen gels[1,2] and are associated with the loss of bone in periodontal disease. The ability of human mammary carcinomas to break down bone *in vitro*[3,4] has been shown to be caused, in part, by prostaglandin release by the tumours[5] and, in part, by their release of an osteolytically active, non-dialysable material (unpublished results). The possibility that the latter might be collagenolytic in nature was suggested by reports that some neoplasms release collagenolytic activity *in vitro*[6-9]. This prompted our present study of the mechanism of bone breakdown by exogenous collagenase. The investigation has shown that prostaglandin synthesis by bone cells is probably a necessary mediatory step in collagenase-induced bone resorption.

The addition of collagenase to tissue culture medium bathing ^{45}Ca-labelled neonatal mouse calvaria increases their release of ^{45}Ca (Table 1) and results in macroscopically obvious disruption of the calcified matrix, together with connective tissue lysis involving the fronto–parietal suture line and consequent physical separation of the two bones. An overall effect of this treatment is to cause the collapse of the bones on to the supporting grids. The addition of aspirin or indomethacin to the incubation medium containing collagenase causes inhibition of the release of ^{45}Ca, and although lysis of the connective tissue along the suture line

73

Table 1 Effect of collagenase on bone lysis determined in an assay using ^{45}Ca-labelled 4-d-old mouse calvaria as described previously[3]

Experiment	Concentration of collagenase (U ml^{-1})	Inhibitor	^{45}Ca release (test–control ratio)
a	5	—	2.34 ± 0.09
	10	—	2.58 ± 0.03
	15	—	3.31 ± 0.28
	15	Aspirin 10 µg ml	1.32 ± 0.04
	15	Indomethacin 1 µg ml^{-1}	1.46 ± 0.17
b	5 (Live bone)	—	2.39 ± 0.44
	5 (Dead bone)	—	1.15 ± 0.10
c	—	SC19220 25 µg ml^{-1}	0.64 ± 0.04
	15	—	2.72 ± 0.39
	15	SC19220 25 µg ml^{-1}	0.73 ± 0.09

Bones were cultured in Biggers medium containing 5% heat-inactivated rabbit serum (Wellcome Reagents). Collagenase was from *Clostridium histolyticum* (Sigma, type III). Aspirin was added to the medium from a stock solution of pure acetylsalicylic acid in Biggers, and indomethacin was added from a stock solution in ethanol to give a final concentration of 0.01% ethanol. This concentration had no significant effect on collagenase activity in these assays. The bones in experiment *b* were killed by immersion in distilled water for 24 h. SC19220 was provided by Searle Laboratories, Illinois. The results are the mean of four determinations ± s.d.m.

of the frontal and parietal bones continues, no macroscopically obvious breakdown of the calcified matrix occurs This treatment thus protects the bones from collapse other than at the suture line. No significant increase in ^{45}Ca release occurs if the bones are killed by immersion in distilled water before incubation with the enzyme, suggesting that an active cellular response is required, but severe weakening of the suture line is effected. Similar results are obtained using trypsin in place of collagenase.

Aspirin and indomethacin are inhibitors of prostaglandin synthesis[10] and some prostaglandins are known to stimulate resorption in live bone *in vitro*[11]. Although Brown and Pollock[14] found that 1 mg indomethacin ml^{-1} inhibited by 50% the action of collagenase on collagen as measured enzymatically, we found no such inhibition at drug concentrations below 100 µg ml^{-1} (Table 2). Similarly, in the bone assay system neither aspirin nor indomethacin prevented the separation of the bone along the suture lines. Our results suggest therefore that collagenase-induced osteolysis may be mediated by prostaglandins, an observation that is given support by the finding that SC19220, an antagonist of prostaglandin action[15], is able to inhibit the collagenase-induced release of ^{45}Ca (Table 1). Further evidence that prostaglandins probably mediate, in part or whole, the action of collagenase on bone is provided by results which show that increases in the prostaglandin E content of incubation media occur in a dose-dependent manner on addition of collagenase (Table 3).

Raisz *et al.*[16] have presented essentially similar evidence for prostaglandin mediation of complement-dependent stiumulation of bone resorption. It seems likely that a similar mechanism of resorption is shared by collagenase, trypsin

Table 2 Effect of indomethacin and aspirin on collagenase activity

Concentration of collagenase (U ml^{-1})	Inhibitor	Enzyme activity
0.5	—	0.35
2.0	—	0.76
5.0	—	1.00
5.0	Aspirin 5µg ml^{-1}	1.03
5.0	Aspirin 50 µg ml^{-1}	0.98
5.0	Indomethacin 1 µg ml^{-1}	0.93
5.0	Indomethacin 100 µg ml^{-1}	0.97

Enzyme activity is expressed as a ratio of the 5 U collagenase ml^{-1} value. Acid-soluble collagen was prepared as described previously[12]. The method of acetylation and of collagenase assay followed that of Ginslow and McBride[13]. The reaction mixture for the assay contained 2 mg ^{14}C-labelled collagen in a 1-ml volume, and the incubation time was 2 h at 37 °C. Aspirin was added from a stock solution of pure acetylsalicyclic acid in buffer. Indomethacin was added as a stock solution in ethanol and its effects were compared to 5.0 U ml^{-1} collagenase containing the same amount of ethanol.

and complement-sufficient heterologous serum, although stimulation of prostaglandin synthesis by the latter agent may depend on a different process. Inhibition of parathyroid hormone-stimulated bone resorption by aspirin[17] is not of the same order as that found on bone resorption stimulated

Table 3 Effect of collagenase on prostaglandin release by bone *in vitro*

Experiment	Prostaglandin released per bone (ng PGE$_2$ Eq)
Control	< 0.3
Collagenase 15 U ml^{-1}	25.6 ± 20.0
Collagenase 5 U ml^{-1}	8.6 ± 4.5
Collagenase 15 U ml^{-1} + indomethacin 1 µg ml^{-1}	< 0.3
Collagenase 15 U ml^{-1} + indomethacin 100 ng ml^{-1}	< 0.3

Unlabelled bones were used and the Biggers medium was supplemented with 0.5% bovine plamsa albumin (twice crystallised, Armour Pharmaceuticals) instead of rabbit serum to avoid complications with prostaglandins present in the serum. Indomethacin was added in ethanol to give a final concentration of 0.01%; the same amount of ethanol was added to all other cultures. For radioimmunoassay, a neutral lipid extract was followed by ethyl acetate at pH 4.7 (citric acid). The residue on evaporation of this was assayed using an antiserum (gift from May and Baker) raised against prostaglandin E$_2$ (PGE$_2$). Cross reaction was found to be 66% for PGE$_1$, but to be < 2% for PGs F$_{1\alpha}$, F$_{2\alpha}$, B$_2$, A$_1$ and A$_2$. The results are the mean of three determinations ± s.d.m.

by these agents. Indomethacin has been reported to have no significant inhibitory action on the stimulation by parathyroid hormone[16,18]. We have also found (unpublished results) that aspirin and indomethacin do not significantly inhibit bone resorption stimulated by vitamin A or 1,25-dihydroxycholecalciferol (provided by Professor I. MacIntyre). It is probable that the resorption achieved by these agents is not as dependent on prostaglandin synthesis for its perpetuation. Since collagenase is found to be released by bone during parathyroid hormone-stimulated resorption[19–21], however, prostaglandins may have some secondary function in physiologically normal osteolysis.

The digestion of bone matrix collagen by exogenous collagenase forms only one step in the highly coordinated process of bone resorption. To complete matrix breakdown, it is likely that other enzymes derived from the bone cells must act with collagenase extracellularly and that the resulting fragments must be endocytosed to undergo further breakdown. This is the same pattern of resorption as was suggested as taking place on parathyroid hormone or prostaglandin stimulation[22], neither of which is markedly affected by indomethacin. It therefore seems probable that the essential difference between the mechanisms of resorption of collagenase and parathyroid hormone, for example,

is in the manner in which stimulation is achieved. It seems reasonable to assume that it is the initial digestion of collagen which causes the bone cell response to exogenous collagenase. The collagen fragments may cause a bone cell memrane reactions which leads to prostaglandin synthesis, and the resulting increased prostaglandin levels may cause normal bone resorption to ensue. Similar membrane effects have been suggested as being involved in complement-sufficient serum-induced bone resorption[16].

Both prostaglandins and collagenase have been suggested as being responsible for the bone resorption associated with some tumours[5–9,23,24], inflamed gingival tissues[25] and dental cysts[26], and rheumatoid synovial tissue[27,28]. The work implicating prostaglandin release from these tissues indicates that indomethacin may be a suitable agent for inhibition of the resorption. Our results suggest that, although the lytic effect of these tissues might be partially dependent on their release of collagenase, indomethacin may still be equally effective in preventing bone destruction.

Simple model for treating evolution of multigene families

THE mechanism by which coincidental or horizontal evolution occurs in the multigene families (such as ribosomal RNA genes) represents one of the most challenging problems of molecular evolution[1,2]. Smith[3] and Black and Gibson[4] put forward an elegant model of coincidental evolution, assuming homologous but unequal crossing over. They have shown, using computer simulations, that repeated unequal crossing over results in the gradual loss of gene lineages, and that eventually the whole family becomes fixed by a single gene lineage. Here the population dynamics of gene lineages within a multigene family is analogous to the population dynamics of mutant genes within a finite Mendelian population. In this communication I show that a quantitative theory of unequal crossover fixation can be developed based on the mathematical theory of population genetics[5,6], treating the behaviour of mutant alleles in finite populations.

Following Smith[3] and Black and Gibson[4], I consider intrachromosomal crossing over and concentrate on a single chromosomal lineage. Let us assume that there are n gene units within a family and that, initially, each unit is represented by a different gene lineage, so that there are n gene lineages at the start. To simplify the treatment, we assume that the mismatch between the two daughter chromosomes at the time of crossing over amounts to a shift of exactly one unit, so that one gene unit is either added or deleted through one unequal crossing over. We further assume that crossing over occurs at random along the n sites and the duplication and the deletion occur alternately, so that the total number of gene units is kept equal to the initial number, n. This corresponds to the action of natural selection holding the size of the gene family approximately constant. This model is illustrated in Fig. 1. Let us designate two consecutive crossovers (involving duplication and deletion) as one cycle of the process.

Now the problem is to analyse how gene lineages become fixed in the family or lost from it by continued unequal crossovers. This problem is quite similar to that of fixation or loss of mutant alleles in finite populations; the unequal crossover corresponds to sampling of genes at reproduction. Therefore, we can treat the frequency change of gene lineages in a multigene family as we treat the gene frequency change in standard population genetics, and in particular we can apply the diffusion model developed by Kimura[7].

The frequency of a particular lineage in the family after a certain number of cycles of unequal crossovers is denoted by x. Note that, at the start, $x = 1/n$, because each lineage is singly represented in the family at the start. To apply the diffusion equation method in population genetics to our problem, we need to evaluate the mean ($M_{\Delta x}$) and the variance ($V_{\Delta x}$) of the frequency change per unit time (that is per cycle of unequal crossovers in this case). These quantities can be computed using Table 1. From the last two columns of Table 1, we can obtain $M_{\Delta x}$ and $V_{\Delta x}$.

$$M_{\Delta x} = \frac{1}{n}x(1-x) - \frac{1}{n}x(1-x) = 0 \tag{1}$$

$$V_{\Delta x} = \frac{1}{n^2}x(1-x) + \frac{1}{n^2}x(1-x) = \frac{2}{n^2}x(1-x)$$

Table 1 was constructed from the consideration that duplication or deletion by unequal crossover occurs at random on the chromosome, so that the probability that a particular lineage increases its size by one unit by duplication, or decreases its size by one unit by deletion, is in each case equal to frequency.

Once the mean and the variance of the frequency change per cycle are obtained, it is possible to apply Kimura's theory of gene frequency change. Note that the zero mean change ($M_{\Delta x} = 0$) in formula (1) implies that the population dynamics for selectively neutral mutants can be applied. In other words, my model is a diffusion process with a zero mean change and a non-zero variance as given in formula (1) and each gene lineage has equal chance of eventually becoming fixed in the family. Now, the dynamics of mutant frequency change in a finite population is a diffusion process with a mean $M_{\Delta x} = 0$ and a variance $V_{\Delta x} = x(1-x)/2N_e$ in case of neutral genes and in a population with effective size N_e. On the other hand, the
Fig. 1 Diagram illustrating the model.

crossover fixation time of one of the n lineages is equivalent to the time until fixation of a mutant allele excluding the cases of loss in population genetics. Kimura and Ohta[8] have obtained the mean fixation time of a selectively neutral mutant in terms of the number of generations (excluding loss). Therefore by analogy, or by replacing N_e with $n^2/4$ in Kimura and Ohta formula, we get the mean of the crossover fixation time in terms of the number of cycles in the following form

$$t_1(p) = -\frac{1}{p}\{n^2(1-p)\log_e(1-p)\} \qquad (2)$$

where p is the initial frequency of the gene lineage and equal to $1/n$. When n is large or p is small, this formula becomes approximately

$$t_1(p) \approx n^2 \qquad (3)$$

Kimura and Ohta also obtained the variance of the time until fixation of the neutral mutant in finite populations[9]. Again, by replacing N_e with $n^2/4$ in their formula, we get

$$\text{var}(t_1) \approx 0.286n^4 \qquad (4)$$

I have checked the above results by computer simulation and the agreements between the predicted and the observed values are generally satisfactory, both for the mean and the variance of crossover fixation time.

Pursuing the analogy with population genetics, it may be convenient to define a quantity similar to homozygosity. In fact, Smith[3] used the quantity called the clonality in his simulation studies, which is equal to the sum of squares of frequencies of gene lineages, and which is equivalent to the homozygosity;

$$C = \sum_i x_i^2 \qquad (5)$$

where the subscript i indicates the ith gene lineage. The expected change of clonality per one cycle of unequal crossovers can be calculated again analogously with that of homozygosity in finite populations.

$$E\{\Delta C\} = E\{\sum_i (x_i+\Delta x_i)^2 - \sum_i x_i^2\} = E\{\sum_i (\Delta x_i)^2\}$$

$$= (1-C)\frac{2}{n^2} \qquad (6)$$

where E stands for taking the expectation. This formula can be derived by using the formula for $V\Delta_x$ in (1) taking all lineages (that is, all i) of the family into account. Again, $n^2/2$ corresponds to $2N_e$ for the change of homozygosity in finite populations.

The present model may be an oversimplification of the actual process of crossover fixation; in particular it assumes

that the duplication and the deletion occurs by one unit. Smith[3] has considered the cases where the duplication and deletion are allowed to vary by more than one unit and his simulation results suggest that this latitude accelerates the diffusion process. Although the exact theoretical treatment of such cases is difficult, very rough estimation can be done as follows. If the mean number of gene units duplicated or deleted by one unequal crossover is m, then one crossover should correspond to $m/2$ cycles of my model, provided that the arrangement of gene lineages is more or less random along the chromosome. By comparing Smith's results (Fig. 3 in ref. 3) with this estimation, it can be predicted that the random arrangement of gene lineages may be obtained when $m \approx n/10$ or when the allowed latitude (which is approximately equal to m) is roughly 10% of the total number of gene units. This

Table 1 Calculations for derivation of equation (1)

Duplication phase		Deletion phase		Total (1 cycle)	
Change of x	Probability	Change of x	Probability	Change of x	Probability
$+\frac{1}{n}$	x	$-\frac{1}{n}$	x	0	x^2
		0	$1-x$	$+\frac{1}{n}$	$x(1-x)$
0	$1-x$	$-\frac{1}{n}$	x	$-\frac{1}{n}$	$x(1-x)$
		0	$1-x$	0	$(1-x)^2$

follows because the observed crossover fixation time in this case ($\approx 2,000$) corresponds to that predicted by the present model, that is $2/10 \times 10,000$. It should be noted here that Smith stopped his simulations at the clonality of 0.9 or when the frequency of a lineage reached about 0.95. The time required to reach this frequency is slightly smaller but not much less than the complete fixation time[10].

I shall compare Smith's results with my prediction in more detail. He obtained the crossover fixation time of very roughly 8,000 for the case of latitude $(m) = 1$ and roughly 2,000 for $m = 5 \sim 25$. The predicted values by my model become for these cases: 20,000, 4,000, 2,000 and 800 crossovers corresponding to the four values of m (1, 5, 10 and 25). This would seem to imply that, for cases when $m < n/10$, the gene lineages are more clustered than random arrangement and hence the actual crossover fixation time is smaller than the predicted values. This is because the variance of the frequency change ($V_{\Delta x}$) gets larger by the correlated changes in such circumstances. If m is larger ($m > n/10$), the gene lineages become more dispersed than random arrangement and the theory gives an underestimation.

The analyses in this communication are not complete, but they at least provide a theoretical basis for further analysis in quantitative terms of the mechanism of coincidental evolution of multigene families.

I thank Dr Motoo Kimura for discussions and suggestions.

Do increases in enzyme activities during muscle differentiation reflect expression of new genes?

TRANSITIONS from embryonic isoenzymic forms to mature adult forms are known to occur during *in vitro* myogenesis for creatine phosphokinase[1] (CPK) and other muscle enzymes[2]. More recently, similar transitions have been shown to occur for myosin[3,4], and actin[5,6]. Both CPK activity[7,8] and amino acid incorporation into myosin[9–11] increase during the early stages of differentiation *in vitro* when cells fuse to form multinucleate myotubes, and it is tempting to assume that these increases require the production of adult form mRNA after activation of a "battery" of genes for myogenesis[2]. Yaffe and Dym[11] have proposed a model of myogenesis in which mRNAs for characteristic muscle proteins are synthesised before cell fusion and stored in a "masked" form until activated by the fusion process, thus giving rise to simultaneous increases in muscle-specific protein synthesis and cell fusion. We describe here experiments which show large increases in CPK activity at the time of early cell fusion which cannot result from activation of "masked" muscle-specific mRNAs and which do not require adult form mRNAs at all. Using a new technique which allows measurement of low levels of CPK isoenzymes, we have shown that the early increase in CPK activity during the first 2 d of culture is of the embryonic, or brain, form, and only later does the adult muscle form make a major contribution to the total increase in enzyme activity.

Embryonic chick skeletal muscle cells were prepared and grown as described previously[12]. Freeze-thawed cell pellets were extracted with 10% sucrose and samples from the centrifuged extract were assayed for CPK activity and protein as described previously[8] to determine specific activity. Isoenzymes were separated by discontinuous polyacrylamide gel electrophoresis[13] and the total specific activity was distributed among the three forms according to the ratios of the peaks of activity obtained after slicing the gel. Appropriate control experiments show that recovery of activity from the gel slices is independent of enzyme concentration and is the same for muscle and brain forms.

Fig. 1 CPK isoenzyme patterns of extracts from 74 h (●) and 96 h (○) muscle cell cultures. A sample (50 µl) of extract was subjected to electrophoresis at 4 °C on 10% polyacrylamide gels with 5% cross linkage[12] for 3 h at 3 mA per tube. Slices (1 mm) of the frozen gels were placed in standard assay mixture and assayed for CPK activity as described previously[8]. CPK specific activity is expressed as international units (1 IU converts 1 µmol of creatine phosphate to creatine per min of incubation at 37 °C) per mg soluble protein in the original extract.

Fig. 2 Specific activities of the three isoenzymes of CPK (BB, ■; MB, ○; and MM, ●) during the first 2 d of culture. Cell fusion (□, broken line) was determined as previously described[8]. Each point represents a determination from a single gel and the combined data of four separate cell preparations are shown.

Creatine phosphokinase is a dimer of brain-type (B) or muscle-type (M) subunits and skeletal muscle differentiation is accompanied by a transition from BB isoenzyme, through the intermediate MB form, to the mature MM form. Figure 1 illustrates the resolution of the three forms on polyacrylamide gels and the continuing transition between 72 h and 96 h of culture. These results are consistent with those obtained by qualitative staining methods involving fluorescence[1] or colour[2] changes associated with enzyme-coupled reactions. Until now, however, no method has been sufficiently sensitive to study isoenzyme changes during earlier stages of culture when increases in cell fusion and enzyme specific activity are just beginning.

Between 17 h and 42 h of culture, fusion increases from

1 to 20% (Fig. 2) and total CPK specific activity increases sixfold. As Fig. 2 shows, this increase is due almost entirely to the BB embryonic form of the enzyme, the mature and intermediate forms showing little change. Whether the simultaneous increase in cell fusion and BB–CPK activity is anything other than coincidental remains to be determined. Although we, and many others, have shown that apparently normal increases in CPK activity can occur at later stages in the absence of cell fusion[12], this has not yet been established for the early increase described here. Earlier[8], we described a transient increase in CPK activity occurring at the time of the initial increase in percentage fusion and before the much larger increases in enzyme activity which occurred later. It is possible that that transient increase is related to the increase in the BB form described here, although direct comparison is not possible since we now use cells prepared differently which fuse and develop much earlier. In this respect, it is interesting that muscle-forming cultures of mouse teratocarcinoma cells show an increase in CPK at the time of myotube formation, followed by decrease, but without any isoenzyme transition from the BB form[14].

The assumption that muscle-specific forms are also involved underlies experiments in which CPK activity and myosin synthesis were "superinduced" by actinomycin D during and shortly before cell fusion. These experiments have been used to support the model involving prefusion synthesis of "masked" mRNAs for protein characteristic of the differentiated state[11]. We have been able to obtain stimulations of 30–50% of total CPK specific activity (and of total activity per culture) by exposing either 22-h or 42-h cultures to actinomycin D (Sigma, 1 μg ml⁻¹) for 4 h. Although an increase of this size specific for the MM or MB forms would be readily detected by our electrophoretic method at these stages, we have found no significant change in the isoenzyme pattern, suggesting that the stimulation is either nonspecific or involves only the BB form. It is fair to say, however, that Yaffe and Dym[11] used rat cells, rather than chick, in rather different culture conditions and obtained larger stimulations by actinomycin D, but, at the very least, our results argue forcibly for the need to demonstrate the isoenzyme transition before conclusions in terms of stored mRNAs for muscle-specific molecules can be made.

In general, we would advise caution in interpreting data on increases in enzyme activities or synthesis during differentiation in terms of new gene expression until they are shown to be due to the authentic mature form of the protein. In view of reports of isoenzyme-like transitions in myosin heavy chains[3,4], these considerations are also applicable to the interpretation of early increases in myosin synthesis during differentiation[10,11], and may influence conclusions drawn from studies of myosin mRNA during myogenesis, since the myosin mRNA synthesis observed in early cultures[9,15] may be of the form that is not muscle specific.

Inhibitory effect of α-(1→6)-heterogalactan on oocyte maturation of starfish induced by 1-methyladenine

THE surface of the starfish oocyte is thought to carry receptors for 1-methyladenine (1-MA)[1,2], which induces maturation division by some mechanism which is at present little understood. Using α-(1→6)-heterogalactan (HGaln) and α-(1→6)-galacto-oligosaccharides, which strongly inhibit the induction of maturation division by 1-MA, we have now obtained evidence that the receptor for HGaln is on the cell surface. We found that in the presence of HGaln, 1-MA did not activate the cell surface.

HGaln is extracted from the fruiting bodies of *Lentinus edodes* and has a main chain of (1→6)-linked α-D-galacto-pyranose residues, parts of which are substituted in the 2-position with either single L-fucopyranose or D-mannopyranose residues[3]. HGaln gives one peak only on ultracentrifugation (S = 1.55), zone electrophoresis and gel filtration.
Fig. 1 Dose–response curves of the starfish oocytes to 1-MA in the presence of α-(1→6)-HGaln(FC, 0.83%) (●), or α-(1→6)-galactotetraose(FC, 0.83%) (▲), or in the absence of any sugars (○). ■, Dose–response of the washed oocytes by HASW after incubation with 0.83% α-(1→6)-HGaln for 30 min at 0–4 °C. Note the inhibitory effect of α-(1→6)-HGaln and α-(1→6)-galactotetraose on the oocyte maturation. At the star 192 × (5.2 × 10⁻⁶ mM) of 1-MA was mixed with 5% α-(1→6)-HGaln at the same volume for about 1 h at 0–4 °C, and 10 μl of the mixture was added to 20 μl of the starfish oocyte suspension in HASW.

Specimens of the starfish *Asterina pectinifera* were collected from Muro Beach, Japan, and kept in an aquarium at 0–4 °C. Ovaries were removed with forceps in calcium-free Hervst's artificial seawater (HASW), and oocytes were prepared as before[4]. After incubation for 1 h in HASW at 0–4 °C, supernatant was decanted, and the oocytes were resuspended in HASW. This washing procedure was repeated to remove follicle cells. Although oocytes stored at 0–4 °C in HASW maintained their sensitivity to 1-MA at the same level for several days, it was necessary to test this sensitivity before each experiment in order to obtain quantitative results. Serial experiments were
Fig. 2 Chromatography of the mixture of α-(1→6)-galacto-tetraose and 1-MA on Sephadex G-25. The column (2.64 × 85 cm) was washed with 500 ml of redistilled water and re-equilibrated with 1 l of 2/3 HASW. The applied sample contained 0.4 ml of 5% α-(1→6)-galactotetraose aqueous solution, 0.4 ml of 1 mM 1-MA aqueous solution and 0.8 ml of HASW. Elution was carried out with 2/3 HASW. Fractions (5 ml) were collected at a flow rate of 10 ml h^{-1}. ○, A_{260}; ●, carbohydrate measured by the phenol-sulphuric acid method at 490 nm.

performed with the oocytes of one animal. To detect the response of the starfish oocytes to 1-MA, 10 µl of 1-MA dissolved in redistilled water was added from a microcapillary pipette into 20 µl of oocyte suspension dispersed in HASW on

Table 1 Effect of the polysaccharides or monosaccharides that constitute α-(1→6)-HGaln, or oligosaccharides from the partial hydrolysate, on oocyte maturation induced by 1-MA in *Asterina pectinifera*

Test samples	Oocyte maturation (%) mean ± s.e.

In each experiment, the minimum concentration of 1-MA for inducing 100% oocyte maturation was added. This was the most suitable concentration for detecting the inhibitory effect. Concentration of test samples was 0.83%.

α-(1→6)-Mannan was provided by Dr T. Nakajima, Tohoku University.

hole glasses (well size, 22 × 2 mm). The mixture was agitated thoroughly with a fine needle. Whole oocytes and those with broken germinal vesicles (OBGV) that had been induced spontaneously were counted under the microscope within 10 min. Breakdown of germinal vesicles began after 15 min of incubation and ended within 30 min of addition of 1-MA, independent of concentration. Therefore the hole glasses were covered with glass plates and after 30–40 min total OBGV was recorded. Each experiment was carried out three times and the percentage of oocyte maturation was calculated as OBGV induced when 1-MA was added to total oocytes. To test the inhibitory effect, 10 µl of the test solution dissolved in redistilled water was added to 40 µl of oocyte suspension in HASW and agitated. A sample of 10 µl of 1-MA solution in redistilled water was then added within 10 min.

As Fig. 1 shows, these oocytes underwent 100% maturation when 1-MA was added in a final concentration (FC) of more than $8 \times (5.2 \times 10^{-6}$ mM). On the other hand, maturation was completely inhibited by 0.83% (FC) heterogalactan in the presence of the same concentration of 1-MA (FC, $8 \times (5.2 \times 10^{-6}$ mM)). FC of $1,500 \times (5.2 \times 10^{-6}$ mM) 1-MA was needed to induce 100% maturation in the presence of 0.83% α-(1 → 6)-HGaln.

The question is whether the inhibitory effect of HGaln was due to D-galactose, or D-mannose. It was also necessary to exclude nonspecific absorption of polysaccharides on the cell surface. We therefore tested for inhibition by other poly-saccharides in experiments summarised in Table 1.

No inhibitory effect was detected with α-(1→6)-mannan isolated from the mutant *Saccharomyces cerevisiae* X2180 (ref. 5), Dextran T 40 (molecular weight 40,000, Pharmacia), or glycogen from rabbit liver (Sigma). This excludes nonspecific inhibition by polysaccharides of the induction of oocyte maturation by 1-MA. D-galactose, L-fucose and D-mannose

Fig. 3 Electron micrographs of the oocytes of *Asterina pectinifera*. *a*, Normal cell surface of the oocytes. The surface is covered with the continuous vitelline envelope (VE). CG, Cortical granule (×22,050). *b*, Surface of the trypsinised oocyte. The vitelline envelope is almost removed by trypsinisation for 4 h at 24 °C with 1% trypsin solution (Difco, 1:250) dissolved in HASW (×22,050).
were also ineffective at the same concentration. α-(1→6)-Galactobiose, α-(1→6)-galactotriose and α-(1→6)-galacto-tetraose, obtained from the partial hydrolysate of α-(1→6)-HGaln[3], were inhibitory (Table 1). The minimum concentration of 1-MA that induced 100% maturation was $30 \times (5.2 \times 10^{-6}$ mM) in the presence of 0.83%(FC) α-(1→6)-galacto-tetraose (Fig. 1). No gluco-oligosaccharides had any inhibitory effect, even if the binding form was α-(1→6)-linked types as the galactosides. Thus the inhibition was due to phenomena specific to α-(1→6)-galactan or α-(1→6)-galacto-oligosaccharides.

We then considered whether the inhibitor might bind directly to 1-MA in the extracellular space, or in the cytoplasm after penetrating the membrane, or on the cell surface. The first possibility was excluded because when $192 \times (5.2 \times 10^{-6}$ mM) 1-MA was mixed with an equal volume of 5% α-(1→6)-HGaln for about 1 h at 0–4 °C, and 10 μl of this mixture was added to 20 μl of starfish oocyte suspension in HASW, the extent of inhibition was 64.4% compared with 100% with the same concentration of 1-MA (FC, $32 \times (5.2 \times 10^{-6}$ mM)) and α-(1→6)-HGaln (FC, 0.83%) after preincubation of oocytes with α-(1→6)-HGaln.

This was supported by chromatography, using α-(1→6)-galactotetraose because α-(1→6)-HGaln showed trace absorption at 260 nm. A mixture of 0.4 ml of 5% α-(1→6)-galacto-tetraose, 0.4 ml of 1-MA solution and 0.8 ml of HASW was stored at 4 °C for 3 h and adapted for a Sephadex G-25 column $(2.64 \times 85$ cm). Elution was carried out with a 2/3 concentration of HASW. Fractions (5 ml) were collected at a flow rate of 10 ml h^{-1}. 1-MA and α-(1→6)-HGaln were completely separated by the chromatography (Fig. 2).
Fig. 4 Dose–response curve of the trypsinised oocytes to 1-MA and α-(1→6)-HGaln. The trypsinisation was carried with 1% trypsin solution for 4 h at 24 °C. ○, Untreated oocyte, no α-(1→6)-HGaln; ●, untreated oocyte, +α-(1→6)-HGaln; △, trypsinised oocyte, no α-(1→6)-HGaln; ▲, trypsinised oocyte, +α-(1→6)-HGaln. The trypsinised oocytes showed the same degree of response for 1-MA and α-(1→6)-HGaln as the untreated oocytes.

As the S value of α-(1→6)-HGaln is 1.55, it is unlikely that it penetrates the cell membrane. This was confirmed as follows. After pretreatment of oocytes with 0.83% α-(1→6)-HGaln for 30 min at 0–4 °C, they were washed twice with HASW, and their sensitivity to 1-MA was examined. The minimum concentration that induced 100% maturation was about $15 \times (5.2 \times 10^{-6}$ mM) (Fig. 1), far less than the value obtained in the presence of exogeneous α-(1→6)-HGaln. Some of the inhibitory effect, however, remained, even after washing. This suggests that the receptor of α-(1→6)-HGaln is present on the cell surface.

To locate the receptors of α-(1→6)-HGaln and 1-MA, the vitelline envelope was almost removed from oocytes by incubation for 4 h at 24 °C with 1% trypsin dissolved in HASW (Fig. 3b). Then oocytes showed the same degree of sensitivity to 1-MA and the same degree of inhibition as untreated oocytes (Fig. 4). The receptor of 1-MA and α-(1→6)-HGaln may therefore be on the plasmalemma.

Production of 14C- and 11C-labelled biomolecules using ionised gases

To establish a rapid method for eventual use in incorporating 11C into important biomolecules, we have studied the interaction of ionised gases with a number of natural products. Our findings on the degradation of cholesterol induced by ionised gases[1] led us to anticipate that such labelling might occur if the gas contained a radioactive label and we present results with 14CO which verify the feasibility of the method. The same approach could also be used with 11C, a positron-emitter which is too short lived for most conventional organic chemical labelling procedures[2]. The resulting tracer biomolecules should have widespread applications in chemistry, biochemistry, biology and nuclear medicine.

The methods and apparatus are broadly similar to those already described[1]. In brief, the principle is as follows (Fig. 1): 14CO gas is introduced into a vacuum system where it is bombarded by a 190-eV electron beam (E) to yield[3] 14CO+, 14C+, O+, atomic 14C and O, and excited 14CO.

Fig. 1 Principle of the labelling method. Electrons emitted by a filament, F, are collimated by a magnetic field, B, to form an axial electron beam E, which is accelerated towards the cylinder C by the potential V_c and collected on a plate P on further acceleration by the potential V_p. Inside the cylinder C, the electrons collide with 14CO molecules (O) and produce an ionised gas containing atoms, ions and excited molecules. These highly reactive species drift to the inner surface of the cylinder C which is coated with a thin organic film. The reactions occurring on the surface produce 14C-labelled compounds which are analysed by chromatography and crystallisation to constant specific activity.
Fig. 2 Tracing of an autoradiogram after thin-layer chromatography of the ^{14}C products obtained from the interaction of organic substrates with ^{14}CO ionised gas. *A*, The position of the parent compound which was added as a marker is indicated by an arrow in each case. The starting materials were: *a*, oestradiol; *b*, 5,6-dimethyl-benzimidazole; *c*, D-arabinose; *d*, thymine; *e*, glycine. Chromatographic systems were: *a*, benzene–ethyl acetate (3:2); *b*, *c*, methanol–chloroform (4:1); *e*, methanol–benzene (2:3), all on silica gel; and *d*, *n*-butanol–acetic acid–water (80:12:30), on cellulose. *B*, Two dimensional analysis of cholesterol after exposure to ^{14}CO ionised gas. Chromatographic solvents were: I, hexane–ethyl acetate (3:2) and II, chloroform–acetone (95:5). Most of the total activity was recovered in spots 2, 4 and 6. By placing reference compounds with the labelled material before analysis, spots 2 and 4 were found to coincide with cholesterol and cholesterol formate, respectively. The identity of the ^{14}C-cholesterol fraction was confirmed by crystallisation to constant specific activity.
These species drift to the inner surface of the cylinder (C) which is coated with organic material. Reactions with the substrate yield a number of labelled products, as shown by chromatographic analysis (Fig. 2*A*). Steroids, proteins, sugars and a number of heterocyclic compounds were treated thus and gave radioactive products in varying yields, some of which migrated with the starting material. Typically, a 2-min bombardment of 10–100 μg of substrate with carrier-free ^{14}CO gave a total yield of labelled products of up to 1 mCi mmol^{-1}. Figure 2*A* shows autoradiograms obtained from a one-dimensional thin-layer chromatographic analysis of experiments with oestradiol, thymine, 5,6-dimethylbenzimidazole, D-arabinose and glycine. A similar analysis was carried out in two dimensions for cholesterol (Fig. 2*B*) and reveals the presence of six major labelled compounds. Two of these (2 and 4) migrate at the positions of cholesterol and cholesterol formate, respectively. The identity of compound 2 (Fig. 2*B*) as the labelled, but otherwise unaltered, parent molecule was established by crystallisation to constant specific activity of the free sterol and of its acetate derivative (Table 1). ^{14}C-cholesterol yields of up to 0.1 mCi mmol^{-1} were demonstrated in this manner. Although this value may seem low compared with chemical

labelling procedures, the replacement of ^{14}C by ^{11}C with its 10^8-fold shorter lifetime, would increase the activity to as much as 10 Ci μmol^{-1}. Even higher yields can be obtained for some of the secondary products of other substrates. This method thus seems particularly promising for the application of ^{11}C in bioorganic sciences and nuclear medicine.

Erratum

In the article "Antiviral and cell growth inhibitory activities reside in the same glycoprotein of human fibroblast interferon" by E. Knight, Jr (*Nature*, 262, 302; 1976) the first line of column 1, page 303 should read . . . was exercised when observing growth inhibition with im-. . . . and not as printed.

Table 1 Crystallisation of ^{14}C-cholesterol from the interaction of cholesterol with an ionised ^{14}CO gas

Crystallisation		Specific activity (d.p.m. g^{-1})
No.	Solvent	
1	Methanol	13,840
2	Methanol	9,964
3	Methanol	9,341
4	Methanol	9,022
5	Petroleum ether–ethyl ether	8,064
6	Petroleum ether–ethyl ether	7,983
7	Petroleum ether–ethyl ether	8,075
8	Petroleum ether–ethyl ether	7,915
9	Methanol–ethyl ether (3-acetate)	8,131
10	Methanol–ethyl ether (3-acetate)	7,974
11	Methanol–ethyl ether (3-acetate)	8,038

Cholesterol (60 μg) was bombarded as described in the text. Labelled products were recovered from the cylinder C (Fig. 1) with ethyl acetate and diluted with 4.87 g of carrier cholesterol. After the eighth crystallisation, the remaining cholesterol was converted to the 3-acetate and the specific activities were adjusted to the equivalent weight of cholesterol.

Economy and ecology

Peter D. Moore

The Economy of Nature: A Textbook in Basic Ecology. By Robert E. Ricklefs. Pp. v+455. (Chiron: Portland, Oregon, January 1976.) $13.95. *Methods in Plant Ecology.* Edited by S. B. Chapman. Pp. viii+536. (Blackwell Scientific: Oxford and London; Halsted: New York, 1976.) Cloth £15; paper £9.75.

PUBLISHERS of ecological textbooks would do well to consider Gause's principle of competitive exclusion. The cash in a student's pocket is a distinctly limited resource for which textbooks must compete; any new text, to be successful, must carve out a niche for itself in what is already a fairly saturated market. And in so doing it will inevitably displace other texts from that volume of literary hyperspace which they currently occupy. When considering a new text, one must therefore assess its competitive ability in the niche for which it has been designed.

Ricklef's new book is aimed at bridging the gap between the voluminous tests which seek to cover the whole gamut of ecological thought and the brief, sometimes superficial, introductory books. It has a broad coverage, following a very similar sequence to his previous book (*Ecology*, Thomas Nelson, 1973), but the text penetrates far less deeply than that volume. The style is light and readable and is uninterrupted by references to original papers. Some new illustrations, both verbal and pictorial, are introduced, although many of the old ones are retained. There is still a strong emphasis upon zoological and North American examples of the principles described.

Is there a niche for this textbook in the current market? I do not consider it a serious competitor with the variety of good textbooks currently available (including Ricklefs' *Ecology* and also Colinvaux, *Introduction to Ecology*, Wiley, 1973; *Ecology*, Krebs, Harper and Row, 1972; *General Ecology*, McNaughton and Wolf; Holt, Rinehart and Winston, 1973) for that portion of the 'resource' provided by British University students of biology. The low level of numerical treatment and the lack of references will prob-

ably cause it to fail in this respect. It is not a textbook which generates a critical approach to the data and the conclusions presented; therefore, I do not think that it will displace any weightier text from this portion of its niche. It may appeal to the broader-based groups of students possibly proceeding along paths encompassing humanities and environmental studies. Here its neglect of the numerical approach may be an asset. In this narrower niche, however, is the resource adequate to support a large population—that is how big is this specialised market? Where competition is weak it is often, although not invariably, due to low resource availability.

The second book, edited by Chapman, is making an overt bid to fill a specialised, relatively narrow niche in the textbook community, that of methodology in plant ecology. A wide range of disciplines, and methods within these disciplines is covered and, since each has a separate author, one might expect a degree of patchiness. The chapter on history of vegetation covers an enormous range of ideas, methods and techniques, but never in sufficient depth to provide an adequate laboratory manual. The key to pollen grains is inadequate, inaccurate and misleading. The description of vegetation is dealt with far too briefly, in the following chapter. Several good textbooks are now available on this subject and this short survey adds little new.

The chapter on production ecology is useful in that it explains very clearly and precisely the basis of productivity estimation and the various growth formulae that can be used. Once again it provides background information and methodological appraisal, but space (presumably) does not allow the detailed descriptions of techniques which would be required by neophytes.

Other topics covered include physiological ecology, soils, climatology, chemical analysis and data collection systems. In almost all cases the sheer pressure of space results in the abbreviation of technique description, although references to the literature are always numerous. The imposed brevity, however, does mean that the serious student of any specialised discipline is likely to look elsewhere for information, often to a text specifically on the required techniques. Competitive displacement is therefore an unlikely outcome of this publication. There remains the question of whether the gathering of all these varied techniques under a single cover might provide the book with a distinct niche of its own. I fear that this is unlikely; it may find its way into libraries or on to a few private shelves, but I cannot envisage its being bought by students; and this is where the real resource lies. ☐

Peter Moore is a lecturer in the Department of Plant Science at King's College, University of London, UK.

Pollution control

The Estimation of Pollution Damage. (Studies in Environmental Pollution.) By P. J. W. Saunders. Pp. 126. (Manchester University: Manchester, April 1976.) £6.95.

NO-ONE approves of pollution. Unfortunately, however, its control is not simple. A great deal of effort and money may be devoted to reducing the amount of some toxic substance in our environment, with little or no useful effect, because preliminary studies have not been made to find out what, if any, harmful effects the

substance is really producing. Our resources are clearly insufficent to deal with every possible source of pollution, and it is therefore essential that we discover which are the greatest danger, and concentrate, first, on their control.

In this book Dr P. J. W. Saunders of the Natural Environment Research Council, and formerly of the Pollution Research Unit at Manchester University, sets out to show how the real, harmful effects of pollution may be measured, so that effective control measures may be planned. The book

is primarily intended for students and administrators concerned with this subject, although it can also be recommended to the more studious members of the wider public who are often so vocal about environmental problems.

Dr Saunders defines pollution as "the introduction by man of waste matter or surplus energy into the environment which directly or indirectly causes damage to man and his environment, *other than* himself, his household, those in his employment or those with whom he has a direct trading relationship". I am unable to understand why self-inflicted, domestic and occupational exposures are excluded except where they interact with other types of pollution. It may be more difficult to evaluate this type of damage in cash terms but they

are equally serious and equally necessary to control.

The amount of information condensed into this small book is quite remarkable. The whole field of air, water, soil and of estuaries, and the specific problems caused by persistant pollutants is summarised in under 20 pages. Global problems are dealt with in about the same space. The remainder of the text describes the many techniques involved in estimating and measuring pollution, with a number of well-chosen practical examples. The extreme compression does not make for easy reading, which may discourage less-informed readers. Students who often only receive a superficial introduction to this subject will benefit most from its content.

Kenneth Mellanby

Changing spectrum for crop plants

Evolution of Crop Plants. Edited by N. W. Simmonds. Pp. xii+339. (Longman: London and New York, 1976.) £14.00.

THIS is an excellent book in which the title is used in its widest sense to convey the whole spectrum of a crop's development from origin to modern varieties, and its present and future potential role in the changing demands of world agriculture. Not since De Candolle has a book attempted to cover all the major and many minor crop plants grown in the world today; this book should therefore prove invaluable to all those involved internationally in crop improvement programmes.

The book is multi-authored, with 86 chapters detailing individual crops, arranged alphabetically by family, with the last two covering timber trees and minor crops. Each has an introduction and four sections on cytotaxonomic background, early and recent history and prospects, ending with a bibliography listing key and source references. Chapters range from 2,000–6,000 words depending on agricultural importance and depth of evolutionary understanding.

The absolute merit of individual chapters must be judged by the relevant crop specialist. All combine a range of scientific disciplines in framing a crop's history in a concise and comprehensive manner. In some instances emphasis on the former has produced some formidable terminology in the cytotaxonomic section (for example, Papaya, ch 8, and Fig, ch 59) and early history section (in

describing early plant migrations); and simplification or additional explanation would be helpful, although in both the regular use of diagrams aids presentation. The recent history and prospects sections detail the application of modern breeding methods in variety development, and attempt to identify the inherent problems for the future. In some cases, however, little mention is made of the local importance of a crop outside its main production area, where different though equally important problems may occur—two examples being cotton and groundnuts in Africa (south of the Sahara).

Of particular note for the future is the recurring theme in many chapters, on crops with a long breeding history, of the poor management in the past of crop genetic resources, resulting in depletion of available genetic variability, which may limit future advances. That this should not be repeated is stressed by a number of authors describing crops which have recently received attention and which, although only now grown in subsistence agriculture, are likely to play a key role in the future in improving living standards in developing countries. It is also evident that there are crops, such as cucurbits and edible aroids, whose potential for production in marginal tropical areas is recognised but as yet little exploited.

I can only agree with the editor's words that the book "concentrates on the particular and, in doing so reveals . . . , how insecure our knowledge often is, how much more work is needed and how often, even now, the right questions have not yet been asked".

H. E. Gridley

H. E. Gridley is a research assistant in the department of applied biology at the University of Cambridge, UK.

Foraminifera

Recent Foraminifera. By Esteban Boltovskoy and Ramil Wright. 515 pp. (Junk, The Hague, 1976.) 125 DFl.

A THOROUGH revision and updating of Boltovskoy's original *Los Foraminiferos Recientes* (Buenos Aires, 1965) has resulted in a comprehensive new text, furnished with well chosen and clearly reproduced figures, a carefully compiled bibliography and a good index, the whole being attractively printed on good paper and sturdily bound. The authors deserve high praise for so successfully summarising such a wide range of information, for always emphasising the significance and practical value of each aspect of the subject, and in producing such a readable book. It can be read from cover to cover with pleasure, or simply dipped into with profit.

No previous knowledge of the foraminifera is assumed, yet the authors quickly introduce the reader to the results of research which were very new when their manuscript was completed (January, 1975). Foraminiferal morphology and biology are clearly and concisely described, the scientific significance of foraminiferal studies is made plain, and the distribution and ecology of the foraminifera are described and discussed in their oceanographic, biostratigraphic and palaeo–oceanographic contexts. Taxonomy, systematics and problems of synonymy are dealt with concisely and realistically. There are most useful chapters covering techniques of collection, preparation, culture and storage, which the authors have tried and tested.

This book is no mere library compilation of other scientists' publications: rather, it is the result of long experience of practical work with foraminifera by the authors themselves. The book is intended for workers of all kinds, from the beginning student to the academic and industrial researcher, for those who have access to large research budgets and to those who can lay hands on only the most simple equipment and most modest resources. The authors succeed admirably.

Of course, there are the inevitable minor errors (a dreadfully confused Fig. 117 is, perhaps, the worst). The book should, however, be compulsory reading for all students of the foraminifera, be they protozoologists or micropalaeontologists, biological oceanographers or biogeographers.

F. T. Banner

Dr Banner is a reader in the Department of Oceanography at University College, Swansea, UK.

Understanding invertebrates

A Functional Anatomy of Invertebrates. By V. Fretter and A. Graham. Pp. vi+589. (Academic: London and New York, March 1976.) £12.50; $31.

THIS is a book meant to be read. It is possible to do so from one end to the other by those who know something about invertebrates; and the experience is refreshing. But when I finished it I wanted to write a different book about invertebrates. This somewhat ungracious comment is a compliment in a way, for those of us who know the authors' many contributions to our understanding of invertebrates will be neither surprised nor disappointed by this book.

It is not possible in so short a space to argue about what is meant by 'functional anatomy' for rather like the words 'physiology' and 'biology', it is interpreted in different ways by different people. So this is a peculiarly individual book and we must be grateful to them for so elegantly setting down their approach after a life-time's experience of teaching and research, and to Academic Press for producing it so well.

How fortunate students are; with Barnes, Meglitsch, and Marshall and Williams as basic texts, and with Barrington, and now this new book, it is possible to obtain a far better understanding of the invertebrates than ever before. I must emphasise the inherent readability of this new book, for so many basic textbooks are so packed with detail that they serve more for reference, or at least can be read with pleasure only in parts.

Fretter and Graham have given us an account of all the more important invertebrates (but excluding protochordates); although exemplary in style and clarity, the illustrations are not numerous and serve to illustrate the text. This is a Koran for the converted and in my opinion it will be appreciated most by those whose interest has already been caught.

How wise it was of Sinauer to put the stereoscan picture of *Didinium* attacking *Paramoecium* on the cover of E. O. Wilson's *Life on Earth.* How much more exciting it would have been in the present case to have ultrastructural details of the coelenterate nematocyst for example, or a stereoscan view of the choanocyte. What a pity there is so little on parasitic protozoa with no life cycle diagrams. Only seventeen pages on land arthropods. No illustration (even) of the cephalopod eye or the octopus brain. I must confess that if I had just left

the sixth-form having used Roberts, Berrill, and Clegg I would think this book, on first impression, was dull, but I would appreciate it more I think, when I had learnt more about the invertebrates. For there is no 'ideal' book to cover so wide a field; there can be no single volume which can provide all a student needs, especially when most of us devote less of the degree course to such basic zoology.

Published at a price most students will be reluctant to pay, it is nevertheless a book no Department can afford to be without. It is a book which provides a stimulating comparison with Barrington and others, and which, I would predict, will be appreciated more and more by students as they come to know the invertebrates better.

R. P. Dales

R. P. Dales is Professor of Zoology at Bedford College, University of London, UK.

Caribbean–Mexican tectonics

The Ocean Basins and Margins. Vol. 3: The Gulf of Mexico and the Caribbean. Edited by A. E. M. Nairn and F. G. Stehli. (Plenum: New York, 1975.)

THIS is the third in a series intended to document the world's ocean basins and their margins. Previous volumes have covered the North and South Atlantic Oceans.

The Gulf of Mexico and the Caribbean Sea have been the subject of many geological and geophysical studies that have added to the wealth of data obtained by the oil industry in the shelf and onshore areas. Not surprisingly, however, there is no firm concensus on the tectonic evolution of the area, although two views are held. The mobilist view seeks to explain the evolution of the Caribbean by seafloor spreading and plate tectonics, whereas the stabilists believe that the Caribbean Sea is an ancient oceanic structure.

There are fifteen chapters in the book. The introductory chapter by Uchupi reviews the Physiography of the Gulf of Mexico and Caribbean Sea. The two succeeding and particularly good chapters discuss Geophysical Studies in the Gulf of Mexico (Martin and Case) and Geophysical Studies in the Caribbean Sea. Fox and Heezen present valuable rock dredge data, and seismic refraction and reflection studies in the Geology of the Caribbean Crust. Other chapters discuss various aspects of Palaeozoic geology around the Gulf of Mexico and Caribbean Sea. There

are detailed reviews of key subjects such as the Northern Termination of the Andes and the Palaeozoic and Mesozoic tectonic belts of Mexico and Central America. Areas discussed in more detail are Cuba, Hispaniola, Jamaica and the Nicaraguan Rise. The Lesser Antilles and Aves Ridge are reviewed by J. F. Tomblin with emphasis on the volcanology, petrology and geochemistry of the arc. T. W. Donnelly concludes the book with a review of critical problems in understanding the Gulf of Mexico and Caribbean Sea.

Like the preceding volumes, this book has its deficiencies. Some of the chapters are little more than dry structural and stratigraphic descriptions of particular areas with little comment on the wider implications. Time has invalidated earlier conclusions—in one case beds previously considered as Permian are now known to be Late Cretaceous. In spite of this criticism, the chapters will be valuable as source material.

A more serious criticism of the book is the absence of any single detailed discussion of the marine geology of the Barbados Ridge and Lesser Antilles arc. Reportedly, wells on Barbados show evidence of imbrication, of obvious relevance in subduction. The Deep-sea Drilling Project results are cursorily treated and would have merited a whole chapter.

One of the authors rightly comments that a synthesis of the land and marine data is required and another that there is a "negative correlation between Caribbean field geology experience and readiness to apply the recent concepts of seafloor spreading". A useful example is the problem posed by the Jurassic igneous rocks of La Desirade situated in the Tertiary Lesser Antilles Arc. Are these rocks *in situ* or are they a tectonically transported slice of old Atlantic ocean crust? In such areas multichannel seismic surveys may resolve such tectonic anomalies.

Multichannel seismic surveys emerge from the book as priority measures for the Gulf of Mexico and Caribbean Sea to resolve such questions as continuity of salt across the Gulf and the distribution of beds below horizon B'' in the Caribbean itself. Such surveys, calibrated by deep-sea drilling, may resolve many of the problems of the stabilism-mobilism controversy, reviewed and briefly discussed by the contributors to the book. **David G. Roberts**

David Roberts is a Principal Scientific Officer at the Institute of Oceanographic Sciences, Godalming, UK. He was recently Co-Chief Scientist on Leg 48 of Glomar Challenger at the Margins of Biscay and Rockall as part of the Deep-Sea Drilling Project.

announcements

Appointment

Mr E. S. Booth, CBE, MEng, FRS, Chairman of the Yorkshire Electricity Board, Leeds, will take over as President of the Institution of Electrical Engineers for 1976/77.

Awards

The Association for Radiation Research has awarded the 1976 Weiss Medal to **Dr Ulrich Hagen** of the Institute of Radiobiology in the Nuclear Research Centre, Karlsruhe for his work on the effects of radiation on biological molecules.

The University of Chicago has awarded the first George Willard Wheland award to **Professor M. J. S. Dewar** of the University of Texas for his achievement in introducing new concepts from quantum mechanics into university courses on organic chemistry.

Meetings

November 8–10, **Function and Biosynthesis of Lipids** (Sponsored by the IUB and PAABS), Sierra de la Ventana, Argentina (Dr Nicolas G. Bazan, Chiclana 508,8000 Bahia Bianca, Argentina).

November 11–12, **Scientific and Technical Publishing in a Multilingual Society,** Luxembourg (Mr J. M. Gibb, DG XIII, European Centre, Kirchberg, Luxembourg).

November 22–26, **Corrosion Problems, Prevention and Practice,** Auckland, New Zealand (Conference Chairman, Australasian Corrosion Association, PO Box 5961, Wellesley Street, Auckland, New Zealand).

December 10, **New Aspects of Epithelial Transport,** London (The Secretary, Dept of Physiology, King's College, London).

December 28–31, **Coconut Research and Development,** Kasaragod, Kerala State, India (N. M. Nayar, CPCRI Regional Station, Vittal 574 243, Karnataka State, India).

January 11, 1977, **Corrosion in Agriculture,** Nottingham (B. Wilton, School of Agriculture, Sutton Bonington, Loughborough, Leics.).

January 26–28, 1977, **Electrical Properties of Biological Polymers, Water and Membranes,** New York (The Conference Director, The New York Academy of Sciences, 2 East 63rd

Person to Person

Myocrisin (sodium aurothiomalate) is said to photosensitise the skin of some patients. Any information concerning such an effect in humans or animals treated with drugs containing gold would be appreciated by Dr R. J. Wilkins, Dept. of Microbiology, University of Otago Medical School, Dunedin, New Zealand.

Smithsonian Fellowships will be awarded to support independent research in residence at the Smithsonian Institute using the collections, facilities, and laboratories and pertaining to research interests of the Smithsonian research staff (anthropology, biology, the earth sciences and the history of science and technology). Fellowships worth $10,000 p.a. and research allowances, are granted to postdoctoral scholars, and predoctoral fellowships, of $5,000 and research allowances, may be granted to doctoral candidates. Applications are due by January 15, 1977.

A limited number of Research Fund grants, (of ~£100) will be awarded for 1977. Application forms, together with the regulations governing the awards, may be obtained from the Education Officer, The Chemical Society, Burlington House, London W1V 0BN, and the closing date for applications is November 1, 1976.

Three awards (consisting of a silver medal and 250 guineas) for work in chemistry will be made to the British chemists who have published the most meritorious contributions in their fields of experimental chemistry. The rules for the award may be obtained from the Local Activities Officer of the Chemical Society, Burlington House, London W1V 0BN. Applications or recommendations must be received by December 31, 1976.

There will be no charge for this service. Send items (not more than 60 words) to Martin Goldman at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

Street, New York, New York 10021).

April 18–20, 1977, **Chemical and Molecular Lasers,** St Louis, Missouri (Deadline for abstracts: January 10, 1977) (Dr W. Q. Jeffers, Helios Inc., PO Box 2190, Boulder, Colorada 80302).

April 18–22, 1977, **Molecular Beams,** Amsterdam (A. E. de Vries, FOM-Institute, Kruislaan 407, Amsterdam, The Netherlands).

April 20–27, 1977, **First International Conference of Science Editors,** Jerusalem (Miriam Balaban, PO Box 4059, Jerusalem, Israel).

May 4–6, 1977, **Ozone Technology,** Paris (Deadline for abstracts: October 31) (International Ozone Institute, European Committee Secretariat, 52 rue d'Anjou, 75384 Cedex 08 Paris, France).

July 24–30, 1977, **40th Annual Meeting of the Meteoritical Society,** Cambridge, UK (Dr E. R. D. Scott, Department of Mineralogy and Petrology, Downing Place, Cambridge CB2 3EW).

August 15–19, 1977, **International Conference on Applied General Systems Research: Recent Developments and Trends,** Binghamton, New York (George J. Klir, School of Advanced Technology, State University of New York, Binghamton, New York 13901).

August 30–September 1, 1977, **Dopamine** (ISN satellite symposium) (Dr P. J. Roberts, Department of Physiology and Biochemistry, University of Southampton, Southampton SO9 3TU, UK).

September 13–16, 1977, **Unconventional Photographic Systems,** Oxford (G. W. Smith, Ozalid (UK) Ltd, Langston Road, Loughton, Essex, UK).

September 14–16, 1977, **Quantum Electronics,** Southampton (Deadline for papers: May 31) (Dr H. C. Hanna, Department of Electronics, University of Southampton, Southampton, Hants SO9 5NH).

September 28–30, 1977, **Platelets: a Multidisciplinary Approach,** Florence (Dr G. de Gaetano, Laboratory for Haemostasis and Thrombosis, Instituto di Richerche Farmacologiche 'Mario Negri', Via Eritrea, 62–20157 Milano, Italy).

October 7–11, 1977, **Essential Oils,** Kyoto, Japan (Mr Yasumasa Kato, Secretary General, VII International Congress of Essential Oils, c/o Kyoto International Conference Hall, Takaraike Sakyo-ku Kyoto, 606 Japan).

Too little guidance on the PhD?

TWO-AND-A-HALF years ago the Expenditure Committee of the House of Commons put out a report on postgraduate education in Britain. Many of the recommendations stirred up strong feelings in the academic community, and there was considerable interest in how the Department of Education and Science (DES) would field this full frontal assault on the nature of the PhD. The recently published White Paper 'Postgraduate Education' (HMSO; 28p) is the rather belated reply.

The Expenditure Committee's most headline-catching suggestions were in the field of postgraduate financing. It had suggested that there should be at least an element of repayable loan in student awards above some basic minimum. This idea finds little favour with the DES and there seems no reason to resurrect it in the near future. But it was not in student finances that the strongest feelings were aroused; it was in the proposals that "pre-experience" students should be discouraged from taking non-vocational postgraduate courses but encouraged into vocational courses leading to qualifications which would be a prerequisite for entry to a career. These suggestions stemmed from the committee's view that "postgraduate education should be shaped, not by student demand alone, but principally by the needs of the economy and of society as a whole".

The Government "broadly accepts" this view in its reply; resources for postgraduate education should be provided "primarily in order to meet the country's need for trained manpower". It accordingly defends itself by pointing to the many moves that are being made to shape postgraduate education towards vocational ends, and remarks that "it would be an over-simplification to regard research training leading to the PhD as non-vocational". And yet having apparently gone a long way down the road to manpower planning in the postgraduate sector, the government then declares that "the content and balance of postgraduate training, in all its complexity, are best left to the autonomous interaction of the institutions themselves, the research councils and employers". It looks suspiciously inconsistent with manpower planning to expect that universities can work out individually how to do their bit to meet the country's and society's need for trained manpower; and it suggests that the DES, for all its waiting to hear the views of (unnamed) relevant bodies before venturing to put its own position forward, has succeeded only in compiling a hurriedly cobbled-together case for seeming to worry about the needs of the nation while actually defending the *status quo*.

In the face of the committee's assault, the DES should have come out fighting. What evidence is there that manpower planning makes sense when it comes to controlling the intake of prospective PhD students? The Expenditure Committee found a few representatives of industry prepared to say that PhDs didn't interest them; but if they had looked in other directions they would have found industrialists prepared to say just the opposite. The Civil Service, another major employer, would equally not be of one mind. With such variability in opinions there seems little sense in trying to evolve any major strategy to switch the emphasis in postgraduate work. It is difficult to believe that there is anything like enough evidence to allow the DES to start matching postgraduate education to the "needs of the economy and of society as a whole".

A somewhat worrying omission from the DES's response is any obvious rejoinder to the committee's view that the number of pre-experience students should be "considerably" reduced. It is indeed true that the number of awards being granted for postgraduate research is slightly in decline at present, and one wonders what it will lead to. Will the downward trend be allowed to continue even if and when the economy picks up? The DES paper mentions only "some areas of study such as mathematics or non-clinical medical research" as being hindered by a student having to take a break after a first degree. It then goes on to promise a higher proportion of post-experience students. The whole looks a little ominous. Maybe we have too many young PhD students; maybe manpower planning would work. One would need more than this White Paper to be convinced, however. The DES, in its stern effort to show what it is doing for the GNP, might too easily abandon education for training.

Flashes in ashes

Allan Piper considers the biggest and most promising of five new energy projects sponsored by the International Energy Agency (IEA).

THE opening earlier this week of a London headquarters for a new National Coal Board (NCB) subsidiary will probably cause no more than a passing ripple in the whirlpool of international energy affairs. Few people can have heard of NCB (IEA Services), and fewer still will know what it represents. But its potential long-term impact on the global energy scene should not be underrated.

In the rush to develop new energy technologies, coal, once in decline as a major energy source, has assumed a renewed importance. Under its Ten Year Plan the NCB aims to boost UK coal production by 15% over the next decade. The US plans to expand its coal industry by a factor of three. Elsewhere—in Europe, the Soviet Union and Australia—similar production drives are getting under way.

But bringing coal out of the ground is one thing; how best to use it is another. The value of coal lies not only in its potential as a fuel. It also shows massive promise as a chemical feedstock, and as a source of premium grade hydrocarbons. Much research is needed—and it is here that NCB (IEA Services) comes in. Set up by the NCB last Novermber, it will look after coal research in Britain for the IEA. Five projects, costing an overall £15 million, have already come its way. Four of them are relatively modest: costing an annual £1 million or so, they involve merely the collection of information for the next five years, keeping the ten nations involved abreast of economic and technological developments.

The fifth project is by far the largest and most promising. It involves the design, construction and operation of an 85 MW fluidised bed combustor on an old NCB site at Grimethorpe in Yorkshire. Jointly financed by Britain, the USA and West Germany, the combustor is expected to cost £6 million to build, and a little over £500,000 a year to run during its eight-year life as an IEA test bed—a total of around £10.5 million.

With so much attention being focused in Britain on nuclear power and North Sea oil resources, the true significance of Grimethorpe is likely to pass unnoticed. In the past, fluidised combustion—an elegant technique for burning fuels efficiently, economically and cleanly—has been sadly undersupported in relation to its technological potential. But Grimethorpe marks a turning point. Through the Depart-

ment of Energy (DEN), which will provide 66% of the cost of Britain's share of the project (the rest will come from the NCB), the UK Government is providing solid backing for the first time.

There are, moreover, preliminary discussions under way between the NCB and leading industrial companies on the early introduction of a 60 MW commercial prototype in addition to the Grimethorpe test bed. Such a step should be technologically possible, and might have been taken already had funds been available. As it is, success in the present talks, and subsequent government approval, could see the first British prototype operating within five years.

Bed of ashes

Fluidised combustors boast advantages that cry out for commercial exploitation. Because they are more compact and efficient than conventional burners, capital construction costs and running costs are lower. They operate at lower temperatures, forming less clinker and slag and thus lowering maintainance costs. They offer operational flexibility: multifuelled combustors can be designed to burn coal, oil and gas, with switchover times measured only in hours. Thus, while they might usefully exploit fluctuations in different fuel prices, they can also remain immune to temporary shortages of particular fuel types. Moreover, by burning extremely low grade coals they could help stretch economic reserves, reducing overall coal production costs.

These benefits spring from the way fluidised combustion works. The underlying principle is startlingly simple. In a fluidised combustor the proportional amount of air involved in fuel burning far exceeds that found in conventional burners. During combustion, tiny fuel particles are continually fed into a bed of fine mineral ash, maintaining a proportion of 1 part fuel to around 200 parts ash. At the same time, an even flow of air is passed upwards through the fuel bed, causing it to act like a turbulent fluid—hence the name fluidised combustion.

As the fuel particles mill around in the airstream they do not stick together because of the low combustion temperature. Consequently they burn extremely thoroughly, distributing heat more efficiently than under ordinary burning conditions. The heat can be utilised either by passing cooling tubes

through the fuel bed, or by using more air than is needed to maintain turbulence, and extracting it from the top of the combustion chamber.

The potential range of application is enormous. As electrical power generators, fluidised combustors might usefully be considered by the Central Electricity Generating Board (CEGB), now busily closing dozens of small, urban coal- and oil-fired plants that could perhaps be converted to complement the nuclear baseload. In industry, fluidised combustors can be used to run small boilers and drying kilns, and pressurised plant can drive gas turbines. They can also be designed as incinerators for sewage sludge, organic and chemical wastes, and everyday municipal rubbish.

With every application the waste heat is easily harnessed. District heating is an obvious area for development here. The DEN, now devoting greater attention to the potential of combined heat and power schemes, is unlikely to overlook this bonus.

The environmental advantages will not be overlooked either. In fluidised combustion the production of SO_2 and nitrogen oxides is easily controlled and minimised. This is because burning temperatures are in the relatively low range of 750–950 °C. On the one hand, this is too cool for the production of most oxides of nitrogen; on the other, it is perfect for the harmless combination of SO_2 with ground limestone placed in the ash bed.

Dusty record

Against that background the poor record of support for research and development (R&D) seems surprising. The CEGB, with potentially so much to gain, withdrew almost entirely from the
Fluidised bed combustor

scene soon after launching pioneering work in the middle 1950s, turning instead to the greater promise then offered by nuclear power and oil. It has since remained involved only in an advisory capacity. Throughout the 1960s the NCB carried the R&D effort virtually alone. The UK Government did not become directly involved until about five years ago, and then only in a minor way with the formation of Combustion Systems Limited (CSL), a tripartite research organisation involving the National Research Development Corporation, the NCB and British Petroleum (BP). The private sector has since shown increasing interest.

The Grimethorpe test bed is not the first in Britain. Progress made by the NCB during the 1960s led to the construction and successful operation of several small experimental rigs at the British Coal Utilisation Research Association (BCURA) in Surrey, and the Coal Research Establishment (CRE) in Gloucestershire. The BP Research Centre at Sunbury on Thames has also been the centre of recent applied research by CSL. Two small commercial plants are already operating in Britain, one of them at Renfrew in Scotland, where the enginering company Babcock and Wilcox runs a 13.5 MW fluidised combustion boiler. The other is used as a grass dryer by an enterprising Lancashire farming family.

Grimethorpe will not represent the first attempt at international collaboration on fluidisation combustion. Work at BCURA in 1970 and 1971 on environmental benefits was sponsored jointly by the NCB and the US Environmental Protection Agency. Over the past five years, following the withdrawal of NCB funding for BCURA, studies on pressurised plant have been supported entirely by the US Office of Coal Research. CSL facilities are currently used by the US Electrical Power Research Institute and the National Swedish Environment Protection Agency, together with many independent commercial organisations. CSL projects are themselves partially supported by grants from the European Coal and Steel Community. With more effort at both national and international level, development might have passed beyond its present point, but the funding was not available.

Perhaps the greatest single setback came in 1971 when the NCB, having decided to stop carrying the R&D burden on its own, failed to win government backing for a planned 20 MW demonstration steam boiler. Only £2 million was involved, and the Advisory Council on Research and Development (then under the Ministry of Power) had just reported favourably on fluidised combustion; initial design studies for the project had been sup-

ported by government grants totalling £200,000.
But the Tory government had only recently come to power, the CEGB, riding the tide of nuclear expansion, was indifferent about the idea and had itself declined to give support, and even the NCB commitment was less than total. Furthermore, export prospects did not look rosy: the US administration for the most part still spurned fluidised combustion, ironically preferring to place massive emphasis on the development of pollution control units for conventional burners.

Dead ahead

Following that setback it was arguably only through the formation of CSL that Britain maintained its technological lead. Not until the coal industry examination of 1974—involving the government, the NCB and mining unions—did fluidised combustion become identified as a priority area for R&D, along with pyrolosis and liquefaction. The decision to support Grimethorpe with DEN funds acknowledged that finding. Orders for hardware should go to UK, US or West German contractors within the next 12 months.

So fluidised combustion looks set to come into its own. In the UK, apart from Grimethorpe and the planned prototype, CSL is actively considering a 66 MW combined heat and power pressurised gas turbine. The British Steel Corporation may well introduce a small unit into its River Dunn works in Yorkshire. The General Electric Company has declared an interest in the

proposed British prototype. And a new joint company, Babcock–CSL has been established as a design and export base.

In the US too, R&D is pressing ahead independently of the IEA project. Work on a $15 million pressurised test bed is due to start near Chicago this autumn, sponsored by the US Energy Research and Development Administration. A lot is at stake. While coal makes up 90% of recoverable fossil fuel researves in the US, much of it has an extremely high sulphur content. Fluidised combustion offers the opportunity to exploit these reserves without violating anti-pollution standards.

The enthusiasm is matched in Europe, in spirit if not with financial backing. Although only West Germany will share the running costs of Grimethorpe with Britain and the US, the other seven member nations of the IEA Working Party on Coal Technology will have access to data. France, alone among the major European nations, has remained cool, but her absence poses no problems.

Fluidised combustion could have tremendous relevance to the future world energy scene. Few now question the crucial importance of nuclear power. And few will argue with the NCB's suggestion that coal's greatest potential lies in pyrolysis and liquefaction. But where coal must be used as a fuel, fluidised combustion looks like becoming the cheapest, cleanest, and most efficient way of using it. As one NCB board member has put it, the greatest innovations are yet to come. □

US ENERGY

Making oil out of money?

A controversial plan to pour billions of dollars of federal funds into commercial development of "synthetic" oil and gas from coal and from oil shale is about to face a crucial test in the US House of Representatives. Colin Norman reports

A SYNTHETIC fuels industry is a keystone of the Ford administration's long range energy research and development (R&D) strategy. The idea is to force-feed its growth in the United States to the point where it could begin to supplement dwindling domestic supplies of oil and gas in the 1980s and 1990s. The plan now arousing controversy is embodied in a bill already approved in differing versions by the Senate and by four separate House committees. It would provide up to $6,000 million to private industry over the next two years in loan guarantees and other financial assistance for the design and construction of large scale production plants.

According to the bill's supporters, chief of whom is Vice President Nelson Rockefeller, the measure is vitally needed to halt the growing imbalance between supply and demand from domestic oil and gas. Without the production of synthetic fuels, the argument runs, imports will inevitably increase as domestic supplies begin to peter out towards the end of the century. And without federal support now, there will be no synthetic fuels industry in place when it is needed.

To the plan's many opponents, however, the idea is a waste of money, an unnecessary subsidy to the already bloated oil industry, and a gross misapplication of energy R&D funds.

The latest five-year R&D plan of the Energy Research and Development Administration (ERDA), published last April, envisages a major role for synthetic fuels in the 1990s, suggesting that they "offer a domestic energy alternative to imported oil and gas". ERDA noted, however, that it will require production of between five and ten million barrels of synthetic fuel a day by 1995 simply to hold imports at their present level, and argued that "for the necessary number of plants to be operating in the mid-1990s, an industrial base on the order of 1 million barrels per day must have to exist by 1985".

ERDA's strategy is thus to press ahead with R&D on advanced technology for producing oil and gas from coal and shale, but at the same time it is urging industry to move rapidly ahead with the design and construction

of demonstration plants using technology already developed. The problem, however, is that such large scale plants are expected to cost about $1,000 million apiece, and, since the economics of the enterprise are difficult to predict, industry is having a tough time raising that sort of money. Hence the argument for Congress to provide loan guarantees and other financial incentives to help the industry get into the synthetic fuels business. ERDA officials describe the situation as similar to that faced by the nascent nuclear power industry in the 1950s.

Opponents of the bill have challenged its justification with arguments which go to the root of the Ford administration's energy policy. Led by Representative Richard Ottinger, a Democrat from New York, they support ERDA's programme for developing advanced synthetic fuel technology —ERDA is already funding a number of pilot scale projects jointly with industry—but they argue that it is premature for the Federal Government to pour vast sums of money into commercialisation efforts.

Those arguments received valuable support late last month from the General Accounting Office (GAO), an investigative body controlled by Congress. In unusually blunt language, the report recommended that "Government financial assistance for commercial development of synthetic fuels should not be provided at this time", and suggested that conservation efforts are likely to be much more cost effective.

The GAO study suggested that oil produced from coal or shale could cost between $18 and $30 per barrel, compared with the current price of about $12 for imported crude. It also estimated that synthetic gas would cost at least twice as much to produce as natural gas. Thus, to make the products competitive, the Federal Government would have to provide direct subsidies in the form of price supports or production assistance, the report suggests.

The GAO report was greeted with jubilation by the bill's opponents, coming as it did on the eve of the House debate. But ERDA officials were understandably less enthusiastic. For example, Robert C. Seamans Jr, the Administrator of ERDA, said in a statement that the report "presents strong conclusions and recommendations to the Congress without a sound underlying basis of analysis supporting them". He took issue with most of the report's conclusions, particularly its

comparison with future synthetic oil prices with present import prices, and suggested, finally, that its publication would be "damaging to the early implementation of our needed energy supply programs".

Equally disturbed was Representative Olin Teague, Chairman of the House Committee on Science and Technology and the chief architect of the bill. Teague called a committee meeting to discuss the report last week, and suggested that he would not bring the bill to the floor unless he is sure that he has sufficient votes to get it through. Later in the week, he said that he would try to get the bill before the full House as soon as possible, indicating that he feels it will pass.

As for the impact of the bill on the synthetic fuels programme, many officials see it as crucial. William T. McCormick, Chief of ERDA's Office of Commercialisation, said last week, for example, that "if this bill doesn't go through, many projects which have been supported by company funds will fold". He added that if the bill fails to pass this year, it will be very difficult to resurrect it next year.

Be that as it may, at least one synthetic fuels programme—the oil shale development effort—is already ailing so much that it may be difficult to revive it simply with a financial injection.

It should be recalled that not too long ago, the vast amounts of oil locked into shale beneath the Rocky Mountains in Colorado, Utah and Wyoming were being touted as the answer to America's energy problems. In January, 1974, the Department of the Interior began to offer small tracts of federal land to the oil industry for testing and development projects. The oil industry paid handsomely for the opportunity, the first 5,000 acre tract fetching a staggering $210 million.

Last month, however, consortia which hold rights to the tracts now leased in Colorado and Utah, withdrew from the programme and asked that the leases be suspended. And late last year, a consortium known as The Oil Shale Company (TOSCO), which was reckoned to be the leader in shale processing technology, announced that it had suspended its own private operations. They all cited the high capital cost of building the plants and a variety of environmental problems as reasons for pulling out.

If Congress passes the Synthetic Fuels Loan Guarantee Bill it may at least help the economics of shale processing, since it would reduce the cost of borrowing funds on the capital market. But, according to an Interior Department official, the prospects for reviving the effort look gloomy. □

GENETICS

Laying the guidelines bare

The long, tortuous process of setting controls on experiments involving recombinant DNA in the United States has taken yet another potentially important turn. Colin Norman reports

THE National Institutes of Health (NIH), the agency responsible for supporting most recombinant DNA experiments in the United States, last week published a 100-page document analysing the possible effects of the safety guidelines which it issued last June. Publication of the document, a legal requirement under the terms of the National Environmental Policy Act (NEPA), is likely to provide an important means of gathering public opinion on the guidelines, but it could also pave the way for some legal challenges to them.

Links between recombinant DNA research and environmental policy may seem a bit tenuous, but the language of NEPA is clear. It specifies that government actions which could have environmental implications should be preceded by an impact statement detailing the environmental risks and benefits associated with that action. Since microorganisms bearing recombinant DNA molecules could affect the health of plants, animals or man, the issuing of guidelines designed to keep such organisms in the laboratory and out of the general environment clearly comes under the terms of NEPA.

That fact was realised in the NIH while the guidelines were in the late stages of drafting, and caused considerable consternation in the agency, contributing to some delay in publication of the guidelines. In the end, however, Donald S. Fredrickson, Director of the NIH, decided to short-circuit the normal NEPA procedure by publishing the guidelines first and the environmental impact statement later. Therein lies a potential problem for NIH.

Already, NIH has received a number of complaints that Fredickson's action has circumvented public participation in the formulation of the guidelines. Among the complaints is a letter from two researchers at the Friends of the Earth, a national environmental organisation. The researchers, Francine Simring and Larna Saltzman, have asked NIH to stop funding all recombinant DNA experiments until the correct NEPA procedure has been followed, arguing that prior publication of the guidelines violates the spirit as well as the letter of NEPA.

Fredrickson has claimed, however, that prompt publication of the guidelines served the public interest better than following the usual NEPA procedure. Until the NIH guidelines were published on June 23, recombinant DNA experiments were proceeding under general guidelines drafted by an international group of geneticists which met at Asilomar, California, early in 1975. The NIH guidelines are in many respects more stringent than the Asilomar guidelines and they also establish a detailed implementation procedure. Thus, the impact statement itself suggests that "the escape of potentially hazardous organisms was more likely in the absence of NIH action". Though such arguments are rational enough, the possibility of a legal challenge should not be completely ruled out.

Nevertheless, the impact statement provides an important addition to the literature on the regulation of recombinant DNA experiments since it provides the first public discussion of the reasons why NIH chose not to follow some courses of action advocated by various groups and individuals. It also contains a discussion of the possible risks and benefits associated with the research, attempts to estimate the probability that some hazards will be realised, describes the guidelines, and outlines the procedure by which they were adopted.

As far as alternative courses of action are concerned, the statement discusses the following:

● No action—simply continue to rely on the Asilomar guidelines as the basis for regulating recombinant DNA experiments. Such a course was rejected because the Asilomar guidelines are considered too lax in some cases, and because there is no formal mechanism to ensure that they will be followed.

● Prohibition of funding from NIH for recombinant DNA experiments. That suggestion was rejected because other sources of funding are available, the potential benefits from the research would be foreclosed, it would "undermine American leadership in the establishment of worldwide safety standards", and the "leadership of the United States in biological research would be threatened". A flat prohibition would also interfere with free scientific inquiry, the statement suggests.

● Restrict all permissible experiments to a few maximum containment facili-

ties—a suggestion put forward most notably by Robert Sinsheimer, Chairman of the Department of Biology at California Institute of Technology. The statement notes that such a course of action would not distinguish between experiments with high potential risk and those believed to pose little, if any, hazard. It would also discourage many experiments and amount to a prohibition on some research because of limited access to such facilities, the statement suggests.

● Prohibit the use of the bacterium *E. coli* in recombinant DNA experiments. Because *E. coli* is a common inhabitant of the human gut, many observers have argued that it is a particularly risky choice as the host for transplanted genes. The statement points out that the particular strain of *E. coli* used in the laboratory has many features which limit its infectiousness. Moreover, it can be genetically altered to reduce its viability even further, as required by the guidelines for some classes of experiments. The statement also defends the decision to permit the use of *E. coli* by noting that no other bacterial species now seems to offer as many safety features.

● The statement also notes that some observers have questioned the decision to permit experiments involving the formation of recombinant molecules from uncharacterised pieces of DNA from warm-blooded animals—so-called shotgun experiments. It also notes that the use of DNA from oncogenic viruses has been challenged. The statement does not defend the decision to permit such experiments, however; instead, it merely notes the objections.

● The environmental impact statement has now been circulated in draft form to numerous scientists and other interested individuals and it is also available on request from the NIH division of environmental services. It is open for comments for 45 days, after which the NIH may convene a series of public hearings. Eventually, the document will be expanded and cast in final form. The comments will also be considered during any future revision of the guidelines.

Because both the risks and the benefits from recombinant DNA experiments are speculative, the impact statement is necessarily vague in places, and is also shot through with value judgments in areas where experimental data are lacking. Critics of the guideline and of the research will therefore find plenty to criticise in the document. A heated and lengthy debate should be anticipated. □

IN BRIEF

NRPB evidence published

The UK National Radiological Protection Board (NRPB), which advises the government on radiation hazards, has urged a fresh appraisal of Britain's approach to nuclear waste management. The board's evidence to the Royal Commission on Environmental Pollution (RCEP), disclosed last week, adds credence to the view that the RCEP's forthcoming report on radiological safety in Britain will itself criticise the relatively disappointing level of UK research into the safe disposal of long-lived radioactive nuclides arising from the nuclear power programme.

The NRPB evidence nonetheless questions recent attacks on international exposure limits for plutonium; and it endorses calls for individually established standards for radioactive discharge from nuclear installations, rather than blanket legislation.

AGR running smoothly

Barring unforeseen setbacks the commercial output of Britain's first Advanced Gas Cooled Reactor (AGR) nuclear power station, Hinkley Point B in Somerset, will have doubled to 1,000 MW by the coming winter. The second of Hinkley B's twin 660 MW reactors, now undergoing final egineering tests, is expected to come online in October, closely on schedule. The first has been performing smoothly at around 500 MW since July, following its switch on eight months ago—outstanding corrosion problems have restricted output to about 80% of the design level. Hinkley B is already producing electricity as cheaply as first generation, magnox nuclear installations, and could eventually become more competitive.

Though the Central Electricity Generating Board last week expressed renewed confidence in the AGR, which it regards as among the safest and 'cleanest' of existing nuclear reactor types, export prospects remain bleak because of its comparatively high capital cost and unproven commercial record.

Uranium fix?

Officials from California's State Energy Commission and Public Utilities Commission have in the past few weeks given the US Department of Justice and the Senate Foreign Relations Committee copies of documents obtained by the Australian Friends of the Earth (and published in the Australian press) apparently revealing the existence since 1971 of an international cartel to fix the price of free world uranium.

The documents, apparently obtained from the files of Mary Kathleen Uranium of Australia, are said to contain references to a meeting in Johannesburg in January 1974 attended by representatives from Australia, South Africa, Canada, France and the London-based Rio Tinto Zinc.

No official comment on the matter was available last week from the Justice Department in Washington, which in July served subpoenas on US and Canadian companies in connection with its investigations of a price ring, or from the Uranium Institute in London, which the documents reportedly suggest might have been intended as the successor to the Uranium Marketing Research Organisation, the name purportedly used by members of the "club" to describe their group.

Solar energy gathering

The planning and coordination of the international effort to develop solar energy was one of the subjects which about 150 scientists from more than 50 countries discussed last week when the World Meteorological Organisation (WMO) and UNESCO held a symposium in Geneva. The symposium, a sequel to one held in 1973 at UNESCO headquarters, also discussed problems, both technical and educational, associated with the conversion of solar radiation.

Nuclear exports overseer

Following the first meeting of the new French Government, the Elysée Palace last week announced the formation of a high-level government council to oversee France's participation in the growing international trade in nuclear technology. It will "define and coordinate sales of nuclear techniques and products".

President Valéry Giscard d'Estaing will head the new committee, which will also include the new Prime Minister, M Raymond Barre, the Foreign, Defence, Finance, Industry and Foreign Trade ministers, and the president of the French Atomic Energy Commission (CEA).

The creation of the new body comes after the call from non-aligned states at their recent conference in Colombo for an oil embargo against France. It also follows the row between France and the US over the sale of a reprocessing plant to Pakistan and the controversy over France's deal involving nuclear plants for South Africa.

Dr Henry Kissinger is meanwhile due to see President Giscard d'Estaing in Paris this week for talks which are expected to include discussions on French nuclear policy.

Biblis to restart

The 1,200 MW Biblis nuclear power station near Essen, West Germany, which was shut down in April after a routine check revealed cracks in the feed-water container, was expected to be back in operation this week, according to a spokesman for the operating utility RWE. News of the fault first emerged in early July, when RWE and Kraftwerk Union, which built the plant, disclosed the cause of the delay. Kraftwerk Union handed the twin pressurised water reactors over in February last year.

Harvesting whale and ·fish populations

from Robert M. May

FROM August 31 to September 9, the Advisory Committee on Marine Resources of the UN Food and Agriculture Organization is holding a Scientific Consultation on Marine Mammals in Bergen. The background papers for the meeting make a fair-sized pile. The major findings are summarised in the reports of four *ad hoc* groups, focusing on large cetaceans, on small cetaceans and sirenians, on seals and marine otters, and on ecological and general problems. A recurring theme is the difficulty of obtaining reliable estimates of population density, and of transferring estimates of population density in one area to another. For example, in reviewing population assessments of Antarctic fin whales, Gambel (conference document ACMRR/MM/EC/9) observes that the International Whaling Commission (IWC) has agreed on a current population estimate of about 83,000 for this species. Gambell notes that this estimate rests, *inter alia*, on a particular model, but that both the model and the numerical estimates of its key parameters are open to question. Moreover there appear to have been "sharp but erratic declines in the fin whale stock indices" in the areas designated III and IV by the IWC, and also a sharp decline in the catch-per-unit-effort in area V; these declines are not consistent with the IWC model. This erratic behaviour is typical of many exploited whale and fish populations, where the amplitude of population fluctuations increases as harvesting rates increase.

In theory and in practice, a central concept in the harvesting of a natural population is the maximum sustained yield, or MSY. The population may be thought of as having some intrinsic nett growth rate, d*N*/d*t*, which depends on the population density, *N*· at low densities, the per capita growth rate is relatively high, but the population is itself small, so that initially the overall growth rate increases as *N* increases; at high densities, the per capita growth rate typically falls, attaining zero when *N* reaches a value *K* (the "carrying capacity" of the environment), and

then becoming negative. Increases in per capita fecundity as population levels are lowered have been documented for several fish and marine mammal populations, although the underlying mechanisms are not always well understood. Possible explanations include the greater wealth of resources in a less crowded environment, and a variety of behavioural responses (some of which, in gregarious marine mammals, can stem from the breakdown in social organisation attendant upon the removal of dominant males or females). The upshot is that the typical plot of total population growth as a function of population density (d*N*/d*t* against *N*) rises from zero at *N*=0, attains some maximum value at *N*=*M*, and then declines back toward zero at *N*=*K*, thereafter remaining negative. A familiar equation which represents this phenomenon is the logistic d*N*/d*t*=r*N* (1−*N*/*K*), but this is only one of many equivalent forms (see for example Holt, ACMRR/MM/EC/29).

In its natural, unharvested state the population will be around the equilibrium value, where recruitment balances mortality, at *N*=*K*. Harvesting constitutes an additional source of mortality, and (provided the harvesting rate is not too high) the population will decrease to some new steady value at which the population gains from the intrinsic growth rate exactly balance the losses due to harvesting. The MSY is achieved by harvesting at a rate such that the population remains around *N*=*M*, that is, by harvesting at a rate equal to the maximum possible nett growth rate. The population may be thought of as a capital sum in a bank, with however the odd property that the interest rate depends on the magnitude of the sum. For sustained yield, one harvests only the interest on the capital; and for maximum sustained vield one arranges that the capital sum shall be that which generates the maximum interest rate.

Two papers in the collection call attention to shortcomings in overly simple notions of MSY, and make important extensions to the theory.

Holt, the convenor of this con-

ference, gives a catalogue of different formulae which have been used to describe recruitment curves. He shows that, on the one hand, available data are rarely of sufficient accuracy to discriminate among the alternative forms, but that, on the other hand, the different forms can lead to significantly different predictions as to MSY. In extreme cases, the harvesting rate that gives the MSY for one curve (for example, a curve skewed to low densities, such as the Beverton and Holt d*N*/d*t* = (1 − *b*)(1 − *N*)*N*/{*N* + (1 − *b*)*N*} with *b*=0 33) can result in extinction of the population if some other curve in fact pertains (for example a curve skewed to high densities, such as the Pella and Tomlinson d*N*/d*t*=b*N*(1−*N*) with *b*=0.67). Holt thus cautions against the uncritical use of MSY calculations to set quotas (see ACMRR/MM/SC/61, and also Allen, SC/57, and Gulland,SC/82). He recommends that a range of different quotas should be set for different stocks of the same species (in different geographical regions), these quotas being set on the basis of a spectrum of estimates of the state of the stock and the form of its recruitment curve; in this way we may hope to learn more.

Holt and the *ad hoc* group IV (ACMRR/MM/SC/5) also note the need to incorporate the effects of random environmental variability into simple population models. One outcome of preliminary explorations in this direction (Beddington, personal communication) is the suggestion that as harvesting rates increase, so too do the relative fluctuations in the population magnitude, and in the catch itself. This goes some way toward explaining an observed property of exploited populations, which was noted above.

Clark (conference document ACMRR / MM / SC / 65, and also *Science*, **181**, 630–634; 1973) makes the important observation that the aim of most commercial fish and whaling industries is not so much to maximise sustained yield, as to maximise the present value, PV, of (discounted) nett economic revenue. To this end, Clark takes the sort of considerations used

for MSY calculations, and modifies them in two ways. First, the harvesting costs are subtracted from the harvest, itself expressed in money units. Second, the present value of the nett economic revenue is obtained by integrating over all future yields, discounting at some appropriate discount rate, δ (which will usually be of the order of the bank interest rate, $\delta = 10$–20%). The aim is now to maximise PV. Although this approach is oversimplified in many ways (it neglects fixed capital costs for example), it is more realistic than classical MSY calculations in that it automatically incorporates the trade-off between short-term and long-term benefits.

Clark then shows that PV is maximised by a strategy which initially depletes the stock to some predetermined value, L, and thereafter harvests it for sustained yield (keeping $N = L$). His remarks are illustrated by numerical calculations for particular assumptions on recruitment and cost curves, but the conclusions are clearly general. Unless we have a combination of relatively low discount rate and relatively high harvesting cost, L will be less than the classical MSY point at $N = M$. The MSY approach will, however, give a good first approximation so long as the discount rate δ is significantly less than the intrinsic per capita rate of population growth, r, for the harvested species. Conversely, if δ is greater than, or of the order of, r then the sustained population value for maximum PV is significantly smaller than the MSY value; $L \ll M$. Clark observes that "international institutions such as the IWC seem to have been established on the assumption that the economic interests of the industry would, if properly channelled, automatically ensure the conservation of the resource". He emphasises that his "analysis indicates that the economic incentive for conservation of such resources may be quite minimal, as far as the commercial industry is concerned. The economic values of the whaling industry, of course, may not coincide with long term economic values of society as a whole".

If, for the moment, harvesting costs are neglected, then a simple but rigorous generalisation of Clarke's results can be given: maximisation of the present value of discounted nett economic revenue of a harvested population will permit the population to persist if, and only if, the maximum per capita population growth rate exceeds the discount rate. If not, PV is maximised by harvesting to extinction. In particular, if the overall population growth curve is logistic, the ratio of maximum PV to MSY sustained populations is $L/M = 1 - \delta/r$ if $\delta < r$, and zero if $\delta > r$. Returning to the

American Indians whaling in the 17th century

image of a fish population as a capital sum in a bank, we see that if the fish are not capable of an intrinsic per capita growth rate in excess of the bank interest rate, then we do better to turn the entire capital sum—the entire fish stock—into real money in a real bank.

For many commercial fisheries in the North Sea, r is indeed sufficiently large for conventional MSY calculations to retain validity as sensible first approximations. But for the Antarctic blue whale r has ben estimated at around 5%, which as Clark emphasises is less than (or at least well within) the normal range of discount rates. Consequently PV may be maximised by fishing such whale species virtually to extinction. The policies pursued by the whaling industries of countries like Japan are not the result of brutal stupidity, but rather are the optimal solutions of problems defined in narrowly economic terms.

Returning to the question of harvesting costs, we note that these will typically be higher per unit catch at lower population densities. Thus it is never economically rational to harvest the last few animals. There remains the worry that this lower economic breakpoint may be below some biological threshold population density, where for geographical or behavioural reasons the population is incapable of maintaining itself; ecologists refer to the existence of such a threshold as an "Allee effect". No such Allee effect has been demonstrated for any marine mammal, so that this economic consideration may contain one gleam of cheer.

Clark's work, which is developed further in his book *Mathematical Bioeconomics* (Wiley, New York, 1976),

is very illuminating. It undercuts the pious belief that the interests of conservation and industry can march together if only the world is seen clearly. The conservationist is essentially a person who does not discount the future, a person for whom $\delta = 0$; for the industrialist, δ is typically the prevailing bank interest rate. Their interests can thus be fundamentally irreconcilable, and no amount of methodological sophistication can help. The overriding decisions must be qualitative social and political ones, on the effective rate at which we discount the future of the world. Then, and only then, can we usefully employ the technical apparatus of MSY, optimum present value of discounted economic revenue, and the like. □

Polycyclic aromatic carcinogenesis

from S. Neidle

OF all the many external agents which can induce cancerous growth in animal cells, polycyclic aromatic hydrocarbons have been the most intensively studied, and indeed this topic has for long occupied a central position in cancer research. Just 200 years ago Pott first described the effects of soot and coal tar in producing a high incidence of scrotal cancer in chimney sweeps—it was not until the 1930s that Kennaway and Cook isolated in pure form the active chemical carcinogen from coal tar and identified it as benzo[a]pyrene, a polycyclic aromatic molecule with five condensed six-

membered rings, and an almost planar molecular geometry. Since then a large number of analogues both potent and inactive have been discovered and/or synthesised.

In spite of considerable research over the past two decades, the molecular basis of action of these compounds is still imperfectly understood, however. An initial problem still without a definitive answer concerns the cellular target of these carcinogens. Both proteins and nucleic acids have been implicated by various workers; however it is now generally agreed that DNA is probably the most likely candidate. Certainly, binding of carcinogenic polycyclics to DNA, albeit at exceedingly low levels, has been well established, largely through the extensive studies of Brookes, Sims and their collaborators. At first sight, it is attractive to conceive of this binding in terms of intercalation between DNA base pairs, as occurs with many planar drug molecules, especially since the hydrocarbons themselves are chemically unreactive. However, there is now clear evidence that the binding is covalent both *in vivo* and *in vitro*. Moreover, intercalation presupposes a planar molecular conformation for the substrate, and there are several examples of very active polycyclic carcinogens which are markedly non-planar and therefore could not possibly act as intercalators, as Glusker, Zacharias and Carrell have shown by X-ray crystallography in the case of 7-chloromethylbenz [a] anthracene (*Cancer Res.*, **36**, 2428; 1976). An alternative hypothesis by Boyland that binding involves an intermediate metabolite, such as an epoxide, has in recent years received widespread general acceptance, and it is now believed that the microsomal "mixed-function" oxidase system is responsible for this metabolic activation into a chemically reactive form.

A region of the polycyclic hydrocarbon molecule considered to be of likely accessibility to such activation is the so-called K-region. Indeed, Grover and Sims have shown that K-region epoxides do bind to DNA both *in vivo* and *in vitro* (*Adv. Cancer Res.*, **18**, 165; 1974), and are more active than the parent hydrocarbons. Weinstein, Harvey *et al* have investigated the *in vivo* binding of such an epoxide, 7,12-dimethylbenz [a] anthracene 5,6-oxide to various nucleic acids and synthetic homopolynucleotides (*Biochemistry*, **14**, 3451; 1975) and showed that there was a preference for reaction with the guanine bases in poly(G) They have now followed up this work with an elegant characterisation of the four major guanosine adducts obtained from separation of the hydrolysis products from the poly(G)–hydrocarbon complex (*Proc. natn. Acad. Sci. U.S.A.*, **73**,

Sounds volcanic

from Peter J. Smith

ACOUSTIC noise from volcanoes must have been heard for thousands of years; yet surprisingly perhaps, no recordings of volcanic sound appear to have been made before the 1950s (in Japan). The history of the scientific study of volcanic noise is not quite as short as that would imply, however. What were probably the first systematic observations were made at Vesuvius in 1906 by Perret, who later continued his work at Etna, Stromboli, Kilauea, Pelee and elsewhere (see *Volcanological Observations*, Carnegie Inst. Wash. Publ. 549, 1950). More recently, Wilcox (in *US Geol. Surv Bull. 965-D*, 1956) has described 11 distinct sounds from Paricutin, and Richards (*J. geophys. Res.*, **68**, 919; 1963), in a wider study, has correlated different sounds with the type of volcanic activity producing them.

But there is more to the study of volcanic sound than simply description and classification. Gorshkov (*Bull. Volcanol.*, **23**, 141; 1960), for example, used microbarograph records to estimate the energy discharged to the atmosphere by several large eruptions, the largest of which was the Krakatoa explosion of 1883 (8.6×10²³ erg). The Shiveluch eruption of 1965 was rather smaller, with only 1.8×10²¹ erg of energy emitted in air waves; but Gorshkov and Dubik (*Bull. Volcanol.*, **34**, 261; 1970) were able to take the analysis of this particular event even further. They found that only 0.10–0.15 per cent of the total kinetic energy derived from the eruption was imparted to the air. According to their estimate, the total energy of eruption was 1.3×10²⁴ erg, most of which was transmitted in the ejecta as thermal energy.

A second quantitative line of enquiry derives from the origin of the sound. The acoustic noise asso-

ciated with volcanic eruptions is, of course, due to the flow of gases—in particular to the interaction of gases with the stationary sides of the volcanic vent and to turbulence in the gases themselves. So as Woulff and McGetchin (*Geophys. J.*, **45**, 601; 1976) point out, analysis of volcanic sound should provide information about volcanic gas behaviour in general and about the velocity history of the gas in particular.

For example, a theoretical study carried out by Woulff and McGetchin suggests that three types of acoustic radiation from volcanic gas flow are possible—monopole, dipole and quadrupole. But the question then arises as to which of these occur in practice. Unfortunately, observational data are sparse; but analysis of recordings of the sound associated with fumarole activity at Volcan Acatenango, a stratovolcano in Guatemala, shows that in this particular instance the radiation is predominantly, if not entirely, dipolar. Extrapolation of this result to other types of volcanic activity is difficult, of course, although the little information available suggests that dipolar radiation should also be predominant in the more violent 'strombollian type of eruption, at least as long as the gas flow is subsonic.

Evidently quantitative studies of volcanic sound are still in their infancy. If acoustic data are to be translated into absolute gas flow velocities it will be necessary to know not only the type of radiation predominant in each particular case but also the constant of proportionality relating velocity to acoustic power in the power law appropriate to that radiation type. Again, the latter information is largely unavailable at present. As an intermediate step, however, there is the hope that even incomplete data will allow the elucidation of relative changes during an eruptive history and thus contribute to an understanding of eruption dynamics.

2311, 1976). In all four adducts, linkage with the polycyclic aromatic is by way of the 2-amino guanine group; two-diastereoisomers are linked to the 5-position of the hydrocarbon, and the other two, are similarly linked to the 6-position.

However, there is increasing and convincing evidence that these K-epoxides are not the major carcinogenic intermediates, at least for some hydrocarbons. Thus, Baird *et al*. have found that 7-methylbenz [a] anthracene and its K-epoxide form significantly different RNA-bound products on treatment with mouse embryo cells in culture (*Cancer Res.*, **36**, 2306; 1976), although

they were unable to actually characterise these products. This is of course not surprising, since the extent of *in vivo* binding is low—at most one hydrocarbon molecule per 10⁴ nucleotide residues. Recently devised techniques of extremely sensitive spectrofluorimetry have helped in this respect. Thus, Daudel *et al*. (*FEBS Lett.*, **57**, 250; 1975) have been able to compare directly spectra of DNA isolated from solution-binding with benzo [a] pyrene, with those from treated mouse skin as well as with spectra from several putative metabolite–DNA complexes. Their results clearly indicate that the K-region 4,5-epoxide is not the species

that reacts with DNA, and instead provide suggestive, though not conclusive evidence that a non-K-region diol-9,10-epoxide is primarily implicated in the metabolic activation of benzo[a]pyrene. Support for this has also come from the similar studies of Weinstein *et al.* (*Biochem. biophys. Res. Commun.*, **70**, 1172; 1976). Weinstein, Harvey and their collaborators have now succeeded in isolating and identifying the adducts from RNA degradation after *in vivo* incubation of benzo[a]pyrene in bovine bronchial explants. The intermediate is the (I) 7β,8α-dihydroxy-9α,10α-epoxy-7,8,9,10-tetrahydro derivative, that is a non-K-region diol epoxide, with subsequent attachment of the 10 position to the 2-amino guanine group (*Science*, **193**, 592; 1976). This compound has also been shown by Newbold and Brookes (*Nature*, **261**, 53; 1976) and Sachs *et al.* (*Proc. natn. Acad. Sci. U S.A.*, **73**, 607; 1976) to be by far the most active mutagen (and therefore carcinogen) of a range of possible benzo[a]pyrene metabolites, including the K-epoxide.

There still remain however, several unanswered questions concerning the ultimate carcinogenic intermediates arising from benzo[a]pyrene, and indeed from polycyclic aromatic hydrocarbons in general. Certainly the diol epoxide is by no means the only reactive intermediate; others remain to be isolated and defined. One should perhaps add that although there is now some evidence that the benzo[a]pyrene diol epoxide is an intermediate in other tissues and species during hydrocarbon binding to DNA, it is not really known whether the same is true for binding to other cellular macromolecules. □

Nucleic acid modification at Erlangen

from Ernest Borek

An international conference on post-transcriptional modification of nucleic acids, organised by Drs Helga and Walter Kersten, was held at the University of Erlangen on July 19–24, 1976.

THE field of nucleic acid modification is burgeoning, making this a most timely meeting. In eukaryotes every species of nucleic acid is modified and the number of known modifications is increasing—six new modifications were reported at this meeting.

W. Kersten (University of Erlangen)

led a round table discussion on the status of tRNA methyltransferases and isoaccepting tRNAs in tumour tissue. In all tumours, except benign ones, the tRNA methyltranferases are altered both qualitatively and quantitatively compared with their counterparts in normal tissue. All tumours examined contain novel isoaccepting tRNAs some of which are also found in embryonic tissue. There is no evidence for extensive hypermethylation of bulk tRNA isolated from tumour tissue, however, but since there are only a few tumour-specific isoaccepting tRNAs in each tumour, each of these purified tRNAs will have to be analysed. The extraordinarily high turnover of tRNAs in tumour tissue has been established recently by reliable analyses of urinary excretion products stemming from the breakdown of tRNA, determined at the US National Cancer Institute. A normal adult may be excreting about 2 mg of dimethylguanosine in his urine per day whereas some patients with Burkitt's lymphoma and cancer of the breast may be excreting as much as 20 mg. If we assume a tumour burden of 1–2 pounds per 100-pound patient, then 1–2% of his metabolising machinery may be producing the breakdown product at a rate 500% higher than a corresponding

Curious atom

from W. T. Toner

A HYDROGEN-like atom in which short-lived elementary particles substitute for both the nucleus and the orbital electron has been detected as the direct product of the decay of a third unstable elementary particle. Professor Schwartz and his colleagues (Coombes *et al.*, *Phys. Rev. Lett.*, **37**, 249; 1976) hope that a study of this most intriguing scientific curiosity will yield new information on the properties of π and μ mesons.

The parent is the longer lived of the two neutral K-mesons, the K_L' which frequently decays into a π meson, a μ meson and a neutrino. In a minute fraction ($\sim 10^{-7}$) of these decays, the oppositely charged mesons are emitted travelling by chance in the same direction with such similar velocities that they remain together long enough to be bound by their mutual electrical attraction. The bound systems are observed after they have passed down a long straight channel swept clear of charged particles by a magnetic field, in an apparatus which detects their charged components when the "π-μ atoms" are dissociated in an aluminium foil.

amount of normal tissue. Some unknown effect of the tumour on the metabolism of the rest of the body cannot be excluded. Such a high turnover of tRNA has also been demonstrated recently in an animal model.

The significance of these aberrations in tumour metabolism is, of course, obscure. They may be part of the oncogenic process or they may contribute to the maintenance of the morbid condition. In view of the many functions and activities of tRNA the problem presents an interesting challenge.

Nothing is yet known about methylation of DNA in tumour tissue. The technology of eukaryotic DNA methyltransferase is still lagging behind the rest of the field, because of the impossibility until recently of preparing soluble enzymes, and there are still conflicting reports of cofactor requirements.

Large strides have been made, however, in the understanding of rRNA modification and processing. J. Dahlberg (University of Wisconsin) identified some of the "spacer" polynucleotides between 16S and 23S rRNA genes as tRNA genes, two of which have been identified as tRNA^{Glu}₁ and tRNA^{Ile}₁. This distribution can account for the coordinate control of the transcription of tRNA and rRNA. R. J. Planta (University of Amsterdam) reported on the species specificity of rRNA modification. The ψ (pseudouridine) content of bacteria, yeast and human rRNA, per thousand nucleotides, is 2.5, 8 and 12 respectively. New modified nucleosides are still turning up. Planta has identified a ψ methylated at N_1 and hypermodified at N_3 by an α-amino-α-carboxyl-propyl moiety. (The latter stems from methionine by the elimination of the thiomethyl group) Nishimura had reported earlier on the modification of U in tRNA by the same fragment of methionine. The versatility of S-adenosylmethionine as the progenitor of modifications is astonishing.

Nishimura (National Cancer Institute, Tokyo) reported his latest studies on the fascinating hypermodified Q base which is present, adjacent to the anticodon, in several tRNAs of many species. What had been thought to be an isomer, Q*, is actually a still more modified form of it. In Q*, position 4 of the cyclopentene ring can be condensed with either mannose or galactose. The method of achieving modification of tRNA by the Q base is fascinatingly complex. In 1972, Farkas (University of Tennessee) discovered an enzyme which inserts guanine into tRNA^{His} of reticulocytes. Nishimura has now found a function for this "guanine insertase"—it introduces a guanine to replace the Q base

without cleavage of the phosphate linkage. Whether an enzyme to reverse the structure, "Q insertase", also exists is not yet known. The complexity of these reactions is significant in view of the known fluctuation in Q base content in *Drosophila* during metamorphosis, and the elevated content of Q* in tumour tissue.

H. Kersten (University of Erlangen) reported on the origin of the methyl groups in thymine of tRNA in Gram-positive organisms. In all but one out of some 20 tested the methyl group is synthesised at the macromolecular level by way of the folate pathway. In all other organisms, including mammals, that methyl group originates from S-adenosylmethionine. On the other hand, the methyl groups in thymine in the rRNA of Gram-positive organisms come from S-adenosylmethionine. It was pointed out that the folate pathway of synthesis must be the more primitive since this is the origin of the methyl group of thymine in DNA. Methylation by enzymes at the macromolecular level is probably a later development since it is the method used to imprint species individuality on DNA and in tRNA. An attempt to resolve the paradox of the two pathways for the methyl groups in tRNA and rRNA was attempted by W. Kersten by the suggestion that tRNA is more primitive than rRNA. This is an interesting suggestion for those interested in the evolution of biomacromolecules.

H. Aschoff and W. Kersten (Erlangen) reported on an 800-fold purification of tRNA 7-G transmethylase from *E. coli*. Starting with kilos of *E. coli* they obtained a protein of 300,000 daltons which produces only 7-meG in tRNA from *B. subtilis* in which a G in the extra arm is not methylated. This signal achievement 15 years after their discovery of the transmethylase highlights the difficulty inherent in purifying these complex enzymes.

One session was devoted to the modification of mRNA in eukaryotes. This area, too, is becoming increasingly complex. For example, D. T. Dubin (Rutgers University) has found a hitherto unknown "capping" of Sindbis virus-specific mRNA with an N₇-dimethyl-7-monomethyl G.

It is interesting to note the impact of policies of governance of science on the particular field covered by the meeting. Pre-eminence in the technology of tRNA modification has now passed from America to Germany and Japan, and one reason for this must lie in the pattern of the granting mechanism in the USA since no one in his right mind would dare tackle such problems on a 2-year NSF grant. There have been two international

conferences on nucleic acid modification in the past 2 years; the first one was convened by Italian colleagues and the current one by German workers. To neither of these conferences was a contributor from Great Britain invited, which may well be because the MRC decided a few years ago that the study of modification of nucleic acids should have a low priority for support. What a pity to exclude the people who initiated modern biochemistry from tackling one of the most challenging problems in the field. ☐

Mysterious meteorites

from M. G. Edmunds

Some forty meteorite chemists and astrophysicists met for an international four-day workshop on isotopic abundance anomalies organised by the Department of Applied Mathematics and Astronomy, University College, Cardiff, and held at Gregynog Hall on August 10–13, 1976.

THE early history of the Solar System has always provided ample scope for speculation, yet recent experimental investigations of the isotopic composition of certain meteorites have provided even more food for thought. A class of meteorites, the carbonaceous chondrites, has traditionally been regarded as the best available sample (except for some volatile elements) of the material out of which the Solar System formed. It came as rather a surprise, therefore, when work in the past few years showed that the relative isotopic abundances of particular elements in these meteorites are anomalous in that they can differ significantly from the so-called "cosmic" abundance ratios which are based on an amalgam of meteoritic, solar spectra and solar wind data. The workshop at Gregynog evolved into discussion of two major topics. The first problem was to sort out the experimental evidence to see exactly which elements really do show isotopic anomalies, and the second was to sift through possible theoretical mechanisms which could account for the origin of these anomalies. The three main possibilities examined were: chemical fractionation of isotopes occurring within some region of the early solar nebula out of which solid planets condensed; the production of particular isotopes in nuclear reactions caused by irradiation of the nebula by

Coated vesicles and clathrin

In a recent squib in these columns, Matus suggested that the protein molecule, "clathrin", which forms the lattice-like coats around coated vesicles (Pearse, *J. molec. Biol.*, 97, 93; 1975; *Proc. natn. Acad. Sci. U.S.A.*, 73, 1255; 1976; Crowther *et al.*, *J. molec. Biol.*, 103, 785; 1976) should be renamed "cytonexin". His reason for this is that E. G. Gray had described a fibrous network in presynaptic terminals which he called a cytonet (*J. Neurocytol.*, 1, 363; 1972; *Brain Res.*, 62, 329; 1973). At that time, Gray noted that the bristles on coated vesicles were indistinguishable (in the electron microscope) from the surrounding cytoplasmic matrix. As Matus states, Gray (*J. Neurocytol.*, 4, 315; 1975) has since repudiated the existence of this cytonet, concluding that it is an artefact of fixation probably arising from the precipitation of cytoplasmic proteins. Despite this, Matus now wishes to preserve this cobweb from the past and make us believe that the cytonet still exists, and that its constituent molecules can be identified by electron microscopy as clathrin, the molecule of which the striking polyhedral coats of coated vesicles are made.

B. M. F. PEARSE

M. S. BRETSCHER

A. I. MATUS REPLIES: Pearse and Bretscher complain about my rehabilitation of the cytonet on the grounds that Gray has repudiated it (*J. Neurocytol.*, 4, 315; 1975). However in that paper Gray ascribed both the cytonet and vesicular coats to a fixation artefact. If we are now to believe that vesicle coats are a genuine feature of the *in vivo* state, as Pearse's work suggests, then Gray's earlier description of the cytonet (*J. Neurocytol.*, 1, 363; 1972) is also unchallenged. Having seen many of Professor Gray's micrographs I have never doubted its existence. However, contrary to the suggestion made by Pearse and Bretscher I have no desire to make anyone believe in the cytonet. I do believe that it is important to point out an alternative to the restricted view afforded by their premature neologism for the coat/cytonet protein.

energetic particles; and the inclusion into meteorites of solid grains from outside the Solar System which had condensed in the stellar explosions which form elements. The grains could hold radioactive atoms and their decay products, carrying the isotopic anomalies from the nucleosynthesis sites.

It seems that definite anomalies have been demonstrated experimentally for several volatile elements. Anomalies for Ne and Xe are already well established. R. N. Clayton (University of Chicago) reported compelling evidence that enrichments of up to 5% in ^{16}O occur, with variations within a given meteorite implying a fine-scale, mineralogically-controlled heterogeneity. R. N. Clayton and J. Kerridge (University of California, Los Angeles) both presented arguments for ^{15}N anomalies, Kerridge concentrating on the fascinating possibility that the ^{15}N content of lunar soil decreases with decreasing age of the soil. Among the welter of possible mechanisms which were discussed for this correlation, the two most promising were time variations in either accretion of interstellar material rich in ^{15}N (for example from grains formed in nova explosions) or in the ^{15}N content of the solar wind incident on the moon and implanted into the soil.

An analysis of the meteorite Arapahoe was reported by F. Podosek (Washington University, St Louis), showing a $^{129}Xe/^{132}Xe$ ratio which is only about half that found in younger chondrites, the lunar soil or present-day solar wind. He argued that the solar nebula must have possessed some inhomogeneity, perhaps by locking up the radioactive precursor of ^{129}Xe in dust and forming Arapahoe out of a ^{129}Xe-poor gas region. D. D. Clayton (Rice University, Texas and University College, Cardiff) was quick to suggest that the ^{129}Xe-rich dust could have been formed in supernova explosions. This idea met considerable opposition, on the basis of the argument that supernova-condensed grains would be unlikely to give the perfectly normal (compared with other chondrites) pattern of release of iodine gas isotopes which is observed when Arapahoe is heated.

Although anomalies in volatiles seem established, the existence of anomalies in refractory elements is much more doubtful. D. N. Schramm (Enrico Fermi Institute, Chicago) reviewed the ^{26}Mg anomaly measurements, and he concluded that there was definite enrichment in addition to chemical fractionation effects. But this was the only refractory element for which an anomaly seemed to be unambiguously demonstrated. Essentially negative results were reported by F. Begemann (Max-Planck-Institut, Mainz) in searches for anomalies in Hg and K, and by L. Grossman (University of Chicago) for Os.

Everyone agreed that meteorites are rather inhomogeneous bodies. R. Lewis and B. Srinivasan (University of Chicago) gave accounts of the separation treatments they have used (with E. Anders) to find within meteorites those minerals which actually carry the anomalous isotopes. One mineral known as "Q", which has been isolated but not identified, contains up to 80% of the trapped noble gases and 50% of the anomalous Xe, although it comprises less than 0.1% of the meteoritic mass. Anders' Chicago group prefers the interpretation that a volatile superheavy element underwent fission to produce the observed Xe anomalies, rather than believing that the minerals carrying the anomalies represent solid material from outside the solar system. O. K Manuel (University of Missouri) repeatedly pointed out, however, that Xe anomalies are correlated with the trapped helium and neon content, implying that some kind of differentiation rather than fission has taken place. Evidence that fission of ^{244}Pu has produced some of the Xe is fairly strong. K. Marti (University of California, La Jolla), P Pellas (Orsay) and Podosek, presented observations of fission tracks, but the number of tracks indicates only a third of the fission required to give all the trapped Xe It is not clear whether the missing tracks have been destroyed, or if an alternative source of Xe is required.

Discussion also ranged over theoretical models for the condensation of solids, both during the formation of the planetary system and in explosive nucleosynthesis events. Grossman suggested that a model for the solar nebula in which the temperature never rose high enough to evaporate all pre-existing solids was at least not inconceivable, and T. Gold (Cornell) pointed out that such conditions could well hold in a slowly contracting disk of material about the Sun. Gold also emphasised that a disk could act as a "flypaper" to collect interstellar material, and that if the disk lasted for an appreciable time then "extra-solar" rather than "pre-solar" solid material could well be captured. M. Newman (Caltech) reported models for accretion of interstellar matter by the Sun, but such effects were likely to be important only if the solar nebula had passed through a dense interstellar cloud. P. M. Solomon (Stony Brook, New York and University College, Cardiff) reviewed the evidence for a large part of interstellar matter existing in the form of a giant dense molecular cloud. and N. C. Wickramasinghe (University College, Cardiff) reviewed data and theories relating to the dust component of interstellar clouds. If a large dense cloud were the nursery of the Solar System, then accretion effects could be important, and be highly relevant to composition of meteoritic matter.

Condensation sequences within the different nuclear zones expanded from a supernova explosion were described by both J. Lattimer (Enrico Fermi Institute, Chicago) and S. Ramadurai (University College, Cardiff). Such equilibrium calculations were recognised as being necessarily rather unrealistic, but did suggest some minerals which might be looked for in meteorites as signatures of dust formed in explosive events. It was also recognised that the mixing between supernova synthesis zones remains an important, but unknown, process in determining the chemical composition of solid products.

Another possible origin for the isotopic anomalies was briefly discussed, the suggestion that a local supernova event at the time of formation of the Solar System sprinkled the isotopes or their radioactive precursors in some inhomogeneous way over the condensing solar nebula. Even the proponents agreed that a model involving nuclear reactions from particle irradiation in the solar nebula ran into extreme energetic difficulties, both in the total amount of energy required and the convoluted shape of the energy spectrum necessary to avoid overproduction of certain species. Although an extensive reaction network reported by S. Woosley (University of California, Santa Cruz) could reproduce some of the anomalies, it certainly could not (for example) explain that of ^{16}O.

More experimental data should soon be available. The elegant experimental techniques of very small scale analysis described by M. Maurette (Orsay) and his colleagues, showing substructure on the scale of 100 Å in 1-μm-sized inclusions, will be able to give chemical and mineralogical information on individual inclusions in the meteorites. Whether real anomalies exist for any non-volatile elements other than Mg remains to be seen, but the results of searches for Si, Ca, Ti, S and Fe are eagerly awaited.

The workshop provided a very enjoyable informal environment for the exchange of ideas. The best interpretation of the anomalies remains unclear—D. C. Black's (*Geochim. cosmochim. Acta,* **36**, 377; 1972) original suggestion of grains from nucleosynthesis sites has its attractions, and has been enthusiastically championed by D. D Clayton and F. Hoyle. But this model still has some serious difficulties, and a lot of detailed mechanism to be worked out At any rate, it looks as if the isotopic anomalies still have much to tell us about how the Solar System formed. □

review article

Electrochemical, solid state, photochemical and technological aspects of photoelectrochemical energy converters

Joost Manassen, David Cahen & Gary Hodes*

Avraham Sofer†

Different aspects of photoelectrochemical energy conversion are discussed. It is shown, by conservative estimates of the energy losses in such a system, that the available photopotential is smaller than the optical bandgap of the semiconductor by at least 1 eV. It is shown that water decomposition using only one photosensitive electrode is energetically unfavourable and that, even when two photosensitive electrodes, are used, the production of electrical current is to be preferred over that of hydrogen.

THE idea of converting solar radiation directly into electrical energy by using electrochemical cells, is gaining in popularity[1-9]. It is a multidisciplinary field, which covers electrochemistry, solid state physics and photochemistry as well as technology and economics[4-9].

From reviewing the publications in these fields it is clear that specialists in one field often are not aware of the implications and restrictions of another field. It is therefore our intention to discuss in this paper some simple general principles rather than to discuss the different aspects in depth as is done in the specialised texts.

Electrochemical aspects

If an electrode is immersed into an electrolyte solution containing a redox couple R/O and is held at a certain potential, two reactions occur at the electrode surface:

(1) The cathodic reaction $O + ne \rightarrow R$ (e = electron, n = reaction valence)

and

(2) The anodic reaction $R \rightarrow ne + O$

If both reactions are rapid and the electrode is held at the equilibrium potential of the couple, a situation is established where the concentrations of R and O are equal. At more anodic potentials, O will be produced, and vice versa. In the case of a slow anodic reaction, for kinetic reasons, however, an anodic overpotential has to be applied to produce O, and the same applies to R when the cathodic reaction is slow. In cases where the cathodic and anodic reactions are one-step processes, we may expect the same kinetic barrier to exist for both reactions and both to be retarded accordingly, but this need not necessarily be so for a multi-stage reaction (see section on energy conversion).

In a photoelectrochemical energy converter, a photoactive electrode is connected with a counter electrode, which should

be as rapid as possible towards the reaction reverse to the one occurring at the photoactive electrode. If the photoactive electrode is illuminated, an electrical current may flow for two quite distinct reasons: one is photocatalysis and the other energy conversion.

Photocatalysis

Photocatalysis can occur only when the system is in a state such that current flow is thermodynamically possible, but is prevented by the kinetics. Such a thermodynamic state may be created, for example, if both electrodes are held at a different potential either by means of an external power source or by keeping anolyte and catholyte at a different composition or temperature. Current can be negligibly small under these thermodynamically favourable conditions, for example because of an overpotential at the photoactive electrode for the redox reaction. The kinetic barrier may be lowered by illumination leading to an increase in current flow. This current flows however because of photocatalysis of an electrochemical reaction and without conversion of light into electrical energy. Another possibility is that the presence in the solution of a material which can react chemically with R or with O, but fails to do so for kinetic reasons. Again, illumination may lower the kinetic barrier and because R or O is consumed, an electrical current will start to flow. In this case we have a photocatalysed fuel cell and again no conversion of light into electrical energy.

Energy conversion

Energy conversion can occur only when illumination changes the thermodynamics of the system, and not just the kinetics as in the case of photocatalysis. In photocatalysis we lower a kinetic barrier and get a decrease of overpotential. In energy conversion we change the energy level of one of the components of the reacting system and must get an underpotential. This means that illumination leads to a situation which in the dark is thermodynamically unfavourable. There is an additional

Table 1 Currents, potentials and power-output of a TiO_2 photo-electrochemical cell, as a function of the counter electrode

Counter electrode	Short-circuit current (μA)	Open-circuit potential (mV)	Maximum power (μW)
O_2 bubbling through solution			
Platinum on high surface carbon black	640	760	200
Platinised platinum	640	760	200
Smooth platinum	530	670	143
Without bubbling			
Platinum on high surface carbon black	640	760	200
Platinised platinum	580	720	175
Smooth platinum	460	640	120

Electrolyte: 1 N KOH. Light source: 150 W tungsten/Iodide. (Intensity equivalent to sunlight incident on the cell.) TiO_2 polycrystalline. Surface: TiO_2 electrode, 0.75 cm²; counter electrode, 4 cm².

condition, however. Imagine that illumination causes an anodic underpotential, which means that O is produced at potentials lower than the equilibrium potential. If the cathodic reaction is rapid, O will be reduced immediately back to R and no current will flow to the counter electrode. The additional condition is, therefore, a slow back reaction at the photoactive electrode.

An attractive system is the redox couple O_2/H_2O, which has been much studied in connection with the photoactive TiO_2 electrode[1–3,6,7–11]. If a TiO_2 electrode is illuminated with light, having an energy larger than its optical bandgap (see below), oxygen is evolved at potentials of more than a volt lower than the thermodynamic oxygen evolution potential. This does not mean however, that in a photoelectrochemical cell with a TiO_2 anode, hydrogen is evolved at the counter electrode. According to the principles described here, oxygen, if present, will be reduced back to water at the counter electrode. Electrodes, which have a low overpotential for oxygen reduction are known from fuel cell technology and in Table 1 (J.M., G H. and D.C., unpublished results) we show how the performance of such a photoelectrochemical cell (PEC) can be improved by changing the counter electrode.

The slow back reaction is ensured in this system because TiO_2 shows a large overpotential for oxygen reduction.

Hydrogen evolution has only been proven in this system by either giving a cathodic bias[7,10] or by having catholyte and anolyte of different composition[7,11]. In both cases a clear distinction has to be made between energy conversion with the assistance of light, and energy conversion solely by light.

In the next section we shall show that to maximise efficiency, overpotentials should be minimised. At the counter electrode this can be achieved by the use of electrocatalysts and a high surface area, as we have seen. At the photoactive electrode we demand a slow back reaction, however, and we have seen that for many cases this means that the forward reaction will also be slow (leading to a sizeable overpotential). An ideal case would be a multistage redox couple, like the O_2/H_2O system, where in principle the forward reaction (oxygen evolution) may be fast and the backreaction (oxygen reduction) may be slow. This, however, is an exceptional case and redox reactions at semiconductor electrodes tend in any case to be slower than at metals. The conditions of a slow back reaction at the photoactive electrode will therefore, in most cases mean that the overpotential of the forward reaction will be appreciable.

Solid state aspects

For an understanding of the origin of the photopotential generated in a photoelectrochemical cell and to estimate its magnitude, it is necessary to understand what is happening in a semiconductor when it is brought into contact with an electrolyte solution and subsequently illuminated. The processes involved can be illustrated schematically by plots of electron energy levels across the semiconductor–electrolyte interface.

Fig. 1a shows the energy levels of an n-type semiconductor in contact with vacuum. When the semiconductor is immersed in an electrolyte solution, containing a redox couple with redox potential E_{redox}, the situation as depicted in Fig. 1b will result, after thermodynamic equilibrium between the two phases is established (that is, the electrochemical potential in both phases is equal). [To put the redox potential on the same energy scale as that used for the semiconductor, both can be referred to the energy level of an electron *in vacuo* at infinity (E_{vac}). It has been shown that E_e (redox) in volts $= E_e$ (redox) in eV + 4.5 eV, that is the energy level for the H^+/H_2 redox couple is 4.5 eV below[1a] that of E_{vac} (4.3 eV according to ref. 13). We assume here, for simplicity, that surface states do not have a role in determining the energetic picture of the electrolyte-semiconductor interface, that is, we deal with the so-called Schottky case. If they do play a part, they can determine the band bending to a greater or lesser extent, independent of the electron affinity of the semiconductor.] This equilibrium will be reached by the passing of majority carriers (electrons in this case) from the semiconductor to the solution, causing a redistribution of positive and negative charge carriers at and near the surface until the Fermi level of the solid equals the redox potential of the solution. Schematically this is shown by a bending of the
Fig. 1 Plots of energy levels: *a*, n-type semiconductor *in vacuo*; *b*, n-type semiconductor/electrolyte in the dark; *c*, n-type semiconductor/electrolyte, when illuminated. SCL: space charge layer; E_c: bottom of conduction band; E_v: top of valence band; E_{vac}: energy level of electron in vacuum; E_F: Fermi level; $E_{(redox)}$: Redox potential of electrolyte; NHE: Normal hydrogen electrode; E_F(photo) Fermi level of illuminated electrode.

valence and conduction bands towards the semiconductor surface, forming the space charge layer.

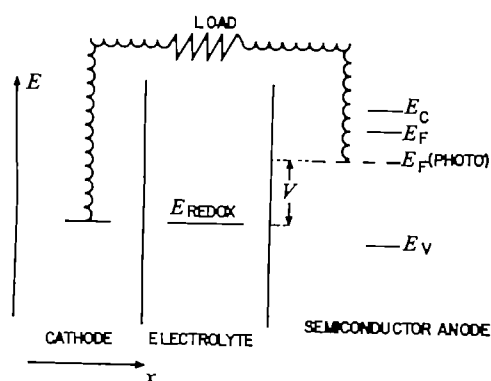
Illumination by radiation with energy content more than E_c-E_v $(= E_g$, the optical bandgap) leads to charge creation and because of the potential difference across the space charge layer, majority carriers (electrons in Fig. 1c) move towards the bulk of the semiconductor electrode and minority carriers (holes in Fig. 1c) towards the electrode surface. This movement counteracts the band bending (that is, causes a partial return to the charge carrier distribution of Fig. 1a) and creates a new situation in which the semiconductor Fermi level is no longer equal to the redox potential of the electrolyte solution. If now the semiconductor electrode is connected with a counter-electrode having the properties defined in the previous section, a photopotential V is established between the two electrodes, which can reach a maximum value of $E_F(\text{photo})-E_{redox}$ (Fig. 2).


Fig. 2 Schematic illustration of the photopotential (V) obtained in a photoelectrochemical cell. The relative positions of E_v, E_F, $E_F(\text{photo})$ and E_v, from Fig. 1 are indicated.

In a working, corrosion-free cell, several kinds of energy losses occur which can be estimated, using Fig. 2 as a guide. The energy balance can be composed of the following units

$$hv = E_c-E_v = (E_{redox}-E_v)+(E_F-E_F[\text{photo}])+(E_c-E_F)+ iR+\eta_c+\eta_p+V \tag{1}$$

where iR are resistance losses in the system, η_c and η_p are overpotentials at the counter electrode and the photoelectrode, respectively.

We shall now make conservative numerical estimates of the different factors involved:

The difference in energy between the potential of the redox couple and the valence band, $(E_{redox}-E_v)$, has to be chosen equal to or larger than λ. Here λ is the reorganisation energy, which has been discussed extensively elsewhere[14-16]. It has to be introduced, because when $(E_{redox}-E_v)<\lambda$ the possibility exists of minority-carrier (hole, in this case)-injection from the redox couple into the semiconductor valence band, which runs counter to the effect we are looking for and may also cause corrosion of the semiconductor.

The value of λ has been estimated variously between 0.4 and 0.8 eV[16,17] and we shall take it here at 0.4 eV.

The difference in energy between the Fermi level *in vacuo* and the Fermi level in contact with electrolyte under illumination, $(E_F-E_F[\text{photo}])$, has to have a non-zero value in order for charge separation to occur. Its allowed value will depend on the width of the space charge layer and the lifetime and mobilities of the charge carriers. To get practical currents, its value may be conservatively estimated at 0.1 eV.

The difference in energy between the conduction band and the Fermi level, (E_c-E_F), may be small, but may also be several tenths of an eV (for TiO_2 it may vary between 0.003 and 0.1 eV (ref. 18)).

The terms iR and η_c can be minimised by practical cell construction and we estimate their combined values, together with that of (E_c-E_F) to be 0.1 eV, which is a conservative estimate indeed.

We have shown in the preceding section that η_p cannot be too small, because of the demand of a slow back reaction and because redox reactions at semiconductor electrodes tend to be slow. Therefore η_p has to be given a larger value and we put it at 0.4 eV.

By substituting these estimates in formula (1), we get

$$hv = E_c-E_v = V+1 \text{ eV} \tag{2}$$

In other words, the difference between the obtainable photopotential and the optical bandgap of the semiconductor is at least 1 eV in a working photoelectrochemical cell.

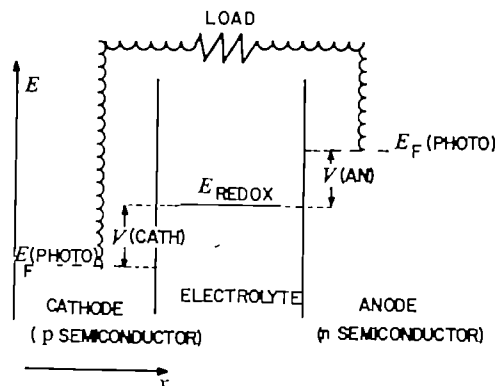
This conclusion has some important consequences. (1) If we want to use a semiconductor with an optical bandgap, so as to give optimal utilisation of solar radiation (~ 1.4 eV: ref. 17), the maximum photopotential attainable will be ~ 0.4 eV. The maximum energy obtainable from solar radiation is about 100 mW cm^{-2}. A PEC converting 10% of this energy would produce 10 mW cm^{-2}, which at 0.4 V means a current of ~ 25 mA cm^{-2}. Such a current makes our estimates for the iR and overpotential losses somewhat optimistic. (2) If our aim is to decompose water, V has to be >1.23 eV and the optical bandgap of the semiconductor electrode >2.23 eV. Therefore to decompose water into H_2 and O_2 we have to accept the loss of an important part of the solar spectrum ($\lambda > 550$ nm). It is possible to get around this problem by using both an n-type semiconductor photoanode and a p-type semiconductor photocathode, in which case two photopotentials, V_c and V_a (see Fig. 3) are obtained, which are additive[10].


Fig. 3 A schematic illustration of the photopotential obtainable when a combination of a photoactive n-type anode and a photoactive p-type cathode is used.

It is interesting that the water decomposition reaction, which occurs naturally in green plant and algal photosynthesis using chlorophyll, also requires two light quanta to obtain the necessary electrochemical potential difference, and that of the light input of 1.8 eV of each quantum, only 1 eV is utilised for the generation of an electrochemical potential difference[11].

Most of the photoelectrochemical cell systems described are complicated by corrosion problems and its prevention is one of the most difficult obstacles to practical realisation of this system. The Cd-chalcogenide based cell, in which the corrosion problem is circumvented by the use of the S/S^{2-} redox couple, shows great promise in this respect[12,13].

Corrosion

It is clear that the electrodes and the redox couple must be entirely stable in the environment of the electrolyte used. There

is however an additional phenomenon, that of corrosion under the influence of light. With CdS the S^{2-} ions are oxidised to sulphur and with ZnO the O^{2-} ions are oxidised to oxygen and the Zn^{2+} ions pass into the solution[24,25]. This means that both photoactive anodes are not stable towards the strong oxidising conditions which exist at their surfaces during illumination. On the other hand, TiO_2 has been shown to be stable under these conditions, as has WO_3 (ref. 26) and Ta_2O_5 (ref. 27). Both cadmium and zinc have only one stable valence state, whereas titanium, tungsten and tantalum are stable in several valence states. It may be, therefore, that one way to obtain stability against photocorrosion in these conditions is by the presence of ions in the semiconductor which can accommodate several valence states.

Photochemical aspects

Problems connected with the heterogeneity of solar radiation have been extensively discussed elsewhere and need not be dealt with here[19].

One has to realise however, that for reasonable conversion efficiency, the light has to be absorbed within the space charge layer, where the necessary potential gradient exists for charge separation to occur. For a material having a decadic absorption coefficient α, 90% of the incident radiation will be absorbed in a layer of thickness

$$L = 1/\alpha \quad (\alpha \text{ in cm}^{-1})$$

A value for α of $10^4 - 10^5 \text{ cm}^{-1}$ is typical of many semiconductors in the strongly absorbing range (both TiO_2 and Ta_2O_5 have exceptionally high absorption coefficients close to 10^6 cm^{-1}) and this would demand a thickness of the space charge layer of about $10^2 - 10^4$ Å. To minimise ohmic losses, we should like to make the semiconductor electrode as conductive as possible. As the space charge layer narrows with increasing conductivity, it can easily reach a stage, at which most of the light passes the space charge layer, with a resultant decrease in conversion efficiency.

Technological and economic aspects

The terms photoelectric energy storage and photoelectric energy conversion are sometimes confused.

A photoelectric energy converter produces electrical energy under illumination and does not store it unless specific storage electrodes can be used[22]. As long as energy production by such a device is small, compared with the overall use of electricity, the electrical current produced can be fed directly into the existing distribution system. This will save fuel, but the capacity of alternative generating capacity will have to remain the same to prevent serious shortages on cloudy days. With the increasing emphasis on the use of nuclear energy, fuel saving will become less important, since fuel costs in a nuclear power station are much smaller than those in a conventional station. Better and cheaper means of storing electricity, however, remain desirable, and hence the practical importance of photoelectrochemical decomposition of water into hydrogen and oxygen.

We have shown that to achieve this with the use of only the photoactive electrode is very inefficient, (no examples have as yet been given in the literature to show that this is feasible without adding energy to the system[7,10,11]). It must be kept in mind that if hydrogen can be produced by the use of a photoactive anode and a reversible counter electrode, most of the energy from hydrogen production can be converted into electrical energy by the use of an oxygen cathode. Fuel cell technology has produced oxygen cathodes with low overpotentials for oxygen reduction under the conditions of low current density which invariably will exist in a solar energy device which does not concentrate the sunlight.

Electrical current may be transported to a central electrolysis plant, which converts water into hydrogen and oxygen at a high efficiency (90% has been claimed[28]). This has to be carefully weighed against the intrinsic lower efficiency of hydrogen production and the appreciable technological difficulties in transporting small quantities of hydrogen (70 ml of hydrogen per (mA cm^{-2}) per min per m^2 of electrode area) leakfree to a central container. If a combination of an n-type and p-type semiconductor is used, both have to exposed to sunlight. This is only attractive when both photoactive electrodes work at about the same efficiency. If one of the two is appreciably more efficient, it is again more favourable to use the most efficient electrode for electricity production alone and to produce the hydrogen in a central electrolysis plant. The only way out of this dilemma would be to use one electrode which absorbs one part of the solar spectrum and positioning it in front of another electrode, which responds to the radiation which has passed the first one.

It seems therefore that the technological prospects of photoelectrochemical decomposition of water are rather dim because there is always the alternative of producing electrical current instead at a higher efficiency and using the current for electrolysis of water in a central plant.

Advantages of photoelectrochemical cells

In the above discussion several inherent disadvantages of the photoelectrochemical cell have been emphasised, which may be less severe for dry photovoltaic devices. There are several arguments however, in favour of pursuing research and development of the photoelectrochemical cell. It has been shown that high efficiency can be obtained, using a thin polycrystalline semiconductor surface. This is because of the much better contact obtained between a polycrystalline solid and a liquid than is possible between two polycrystalline solids, and the "single crystal barrier", which is often used as an argument against cheap solid-state solar cells, does not have to be overcome here. Therefore the production cost of a photoelectrochemical cell can be considerably less than that of dry cells. "Cost" does not only mean the money to be paid, but also the energy-input in production. By mass-production techniques it will certainly be possible to decrease the cost in terms of money of dry photovoltaic cells, but it is much more difficult to bring down the cost in terms of energy and it is in this respect that the photoelectrochemical cell has a chance to compete with dry photovoltaic devices.

γ-ray bursts from thermonuclear explosions on neutron stars

S. E. Woosley & Ronald E. Taam

Lick Observatory, Board of Studies in Astronomy and Astrophysics, University of California, Santa Cruz, California 95064

It is proposed that γ-ray bursts originate from carbon detonations initiated by the accretion of matter on to the surface of a neutron star. The observations are interpreted in terms of this theory. Possible implications for the nuclear powered model of giant X-ray pulses are discussed briefly.

More than three years have now elapsed since the first published report of cosmic γ-ray bursts by Klebesadel *et al.*[1], but in spite of continuous monitoring and observation[2,3] the astrophysical origin of these phenomena still remains enigmatic[4]. Briefly, the dominant characteristics of the observed bursts are:

(1) Total durations of ~ 1–10 s with significant time structure on scales as short as 16 ms.

(2) Integrated burst energies at the earth of 10^{-5}–10^{-4} erg cm^{-2} for events which occur ~ 10 times per yr, with some evidence for more frequent less energetic bursts of ~ 10^{-7} erg cm^{-2} occurring perhaps several times per d (refs 3, 5).

(3) An energy spectrum that can be represented by an exponential from 100 to 400 keV tangent to a power law at higher energies[3]. The spectrum seems typical of a cooling black body of a temperature ~ 2×10^9 K (ref 6).

(4) The distribution of energetic sources seems to be crudely isotropic and uncorrelated with the observed strong X-ray sources, although Cyg X-1 is a possible exception[3].

The short time scale structure of these bursts suggests that they originate from a compact object[7], and the spectrum indicates a possible thermal source. We propose that the observed bursts are produced on the surfaces of neutron stars as a result of violent thermonuclear runaways initiated in accreted nuclear fuels. Attention is focused on the onset of carbon burning which we find, for reasonable choices of parameters, occurs in conditions that are very degenerate and potentially quite explosive. These same conditions have previously been found to result in the detonation of carbon in the core of highly evolved stars and have been investigated as a possible mechanism for the supernova phenomenon[8-13]. Such detonations are characterised by very short time scales and multibillion degree temperatures. Here, by using the gravitational potential well of a neutron star, we find that similar behaviour can occur for critical carbon masses of only 10^{22} g as opposed to the $1.4M_\odot$ usually required for a detonation initiated by self-gravitation.

The model

Consider a $1.4M_\odot$ neutron star of radius 10 km accreting hydrogen and helium at $10^{-10}M_\odot$ yr^{-1}. An accretion rate of this magnitude might be realised by a Roche lobe overflow of a less massive main sequence companion or perhaps by a single neutron star in a very dense cloud or nebula. This object would not appear as a strong X-ray source, and, because of

the softness of the resulting spectrum[14], might be difficult to detect at a distance of, say, 1 kpc. It will turn out that accretion rates of roughly this magnitude are required since the proposed detonation does not seem likely for markedly different values.

If the host neutron star has a strong magnetic field, the material is not accreted in a spherically symmetric manner, but instead accumulates in polar caps of ~ 10^{10} cm^2 or ~ 0.1 % of the surface area[4,15]. Initially any nuclear reactions that occur in this matter act only to strip down nuclei and fragment them. As additional material is accreted, however, compression occurs and nuclear fusion reactions, enhanced by electron screening, commence. Hydrogen burns to helium[15,16] and helium to carbon and oxygen[16]. These burning phases may become unstable, but, whatever the outcome, it is clear that little material escapes the gravitational field of the neutron star. Hansen and Van Horn[16] have found that the density of the helium-burning shell on a neutron star is ~ 10^6 g cm^{-3}. Thus one expects that the carbon formed by this burning will be relativistically degenerate. Because of the high conductivity of degenerate matter, the carbon will be maintained at a temperature close to that of the helium-burning shell. For the assumed accretion rate and geometry one can use the Hansen and Van Horn calculations of nuclear fusion on neutron stars to obtain an estimate for this temperature of ~ 4×10^8 K (Note that, in terms of accretion per unit area, $\dot{M} = 10^{-10}M_\odot$ yr^{-1} on the poles is equivalent to a uniform global rate of $\dot{M} \approx 5 \times 10^{-8}M_\odot$ yr^{-1}.)

It is of some interest to examine the state of this carbon layer after 4×10^{22} g of matter has accumulated: the density at the base of the carbon shell will then be ρ_b ~ 2×10^9 g cm^{-3} (calculated from the equation of hydrostatic equilibrium with pressure support from degenerate electrons). This shell of carbon, ~ 50 m thick, is capped by 1 or 2-m layers of hydrogen and helium containing ~ 10^{14} and ~ 10^{17} g respectively, both with active burning shells. Before reaching this density, the carbon layer is cooled by neutrino emission, with maximal losses in the regions of highest density. A positive temperature gradient will develop, so that conduction acts to heat the dense carbon rather than cool it. Once a density of ~ 10^9 g cm^{-3} is reached, however, the plasma neutrino losses become rather suddenly less effective in cooling, and at a density ~ 2×10^9 g cm^{-3} the nuclear energy generation from carbon burning dominates the neutrino losses. Any increase in density above this value leads to a nuclear runaway[8,9,17]. Because of the high degree of degeneracy, low specific heat, and extreme temperature sensitivity of the carbon-burning reaction the runaway will be quite violent. In the carbon-detonation supernova model, carbon ignites at temperatures and densities almost identical to those described here, and one achieves temperatures > 5×10^9 K and nuclear burning time scales (once a significant amount of carbon has burned) of ~ 1 ms (ref. 8). Not only does carbon burn, but also oxygen and their products as well. Here one

expects the entire layer of carbon to burn on a very short time scale either through a series of carbon flashes[13] or by the formation and propagation of a detonation wave[16]. If a detonation wave propagates the relevant time scale is < 1 ms. Ultimately, species in the iron group are produced and 7.6×10^{17} erg g^{-1} of nuclear energy is liberated. Thus in the case of the model neutron star discussed here, complete combustion of all available carbon releases 3×10^{40} erg. This energy is dissipated through neutrino processes, conduction, convection, and the expansion of the neutron star atmosphere. But unlike the case of a supernova, which it otherwise so closely resembles, the expansion that results from an explosion on a neutron star is negligible. The total energy generated by the explosion is only $\sim 0.5\%$ of the gravitational binding energy of the carbon. Moreover, any energy that goes into expansion is immediately regained on a time scale $\sim 10^{-3}$ s as the material is pulled back by gravity. Thus, the only immediate result of a carbon detonation in this case is to heat material to a very high temperature.

The relevant time scales at this point become very difficult to estimate especially without a detailed numerical model. The incandescent carbon will cool by emitting neutrinos, by conduction to the core and surface, and by convection. The conductivity of the hot carbon ($T \sim 5 \times 10^9$ K) is not as high as it was before the explosion (since $K_{cond} \propto T^2$). We estimate the thermal relaxation time scale for the 50 m of carbon to be $\sim 10^3 - 10^4$ s if cooling occurs by conduction alone, but this is an overestimate since convection will undoubtedly have an important role. Even with a detailed numerical model the physics of convection in a relativistically degenerate electron gas permeated by a 10^{12}-gauss magnetic field would be very uncertain. All one can say at this point is that a cooling time scale of a few seconds does not seem unreasonable.

The emission from the stellar surface may also have an unusual character. As mentioned previously, the layers of hydrogen and helium capping the carbon are very thin, and contain only $\sim 10^{-4}$ of the mass of the exploding carbon. It appears very likely that instabilities and convective overshoot will develop so that hot blobs of burning carbon will break through the surface of the neutron star. There incandescent blobs having temperatures of several billion degrees and dimensions perhaps of several metres will cool by emitting neutrinos and γ rays in times < 1 s. Additional temporal structure may result if the neutron star is an oblique rotator with rotation period less than the cooling time.

Comparison with observations

How do these results compare with the observations? The spectrum, following the above discussion, is that of a rapidly cooling multibillion degree black body, and the short time scale structure in the observed bursts relates to the cooling times of these small hot convective blobs. If one assumes that only 10% of the available energy is radiated in this form, the total photon energy is $\sim 5 \times 10^{38}$ erg. At a distance of 1 kpc this would give rise to an integrated flux at the Earth of $\sim 3 \times 10^{-5}$ erg cm^{-2} in good agreement with observations.

How many such objects would exist within 1 kpc of the Earth? Various arguments involving nucleosynthesis, supernova rates, and pulsar statistics suggest that there are $\sim 3 \times 10^8$ neutron stars in the entire Galaxy. If these are distributed uniformly throughout the Galaxy with a scale height $\lesssim 1$ kpc above the galactic plane one can expect $\sim 10^6$ neutron stars within 1 kpc of the Earth. Of these, perhaps 1% are in binaries. What fraction of the binaries are currently accreting mass at the required rate? This is connected with the mode of mass transfer which could be either a stellar wind, or Roche lobe overflow. If the former is the case, the mass transfer rate from the companion must be $\gtrsim 100$ times the accretion rate, since the neutron star subtends a small solid angle. This suggests that the mass loss rate from the companion is $\sim 10^{-8} M_\odot$ yr^{-1} which is typical for supergiant stars ($M \gtrsim 20 M_\odot$). However the duration of this mass transfer phase is < 10^5 yr (ref. 18). One then expects $10^6 \times 0.01 \times 10^{-5}$ < 1 object at this phase

of evolution. Clearly this is not in accord with the observations. If one considers Roche lobe overflow, a mass loss rate of $10^{-10} M_\odot$ yr^{-1} might be typical for a main sequence star less massive than the neutron star transferring mass on a nuclear time scale. One would then expect $10^6 \times 0.01 \times (0.01-0.1) \sim (100-1,000)$ objects. If the neutron star was formed by a type II supernova, there would be some doubt as to whether the 'desired' system would remain bound. For progenitor masses $\gtrsim 4 M_\odot$ (believed to be a probable lower limit) the binary would probably disrupt since the amount of mass loss in the supernova explosion would be > half the total mass of the initial system[19]. These arguments preclude the existence of γ-ray burst sources as evolving from type II supernovae. It is, however, not implausible that the systems could have evolved from type I supernovae (as, for example, may occur in cataclysmic variable systems)[20]. Accepting the above conclusion, one might expect the sources to be confined to the galactic plane, since the progenitors of the type I supernovae are believed to be old stars in the stellar disk. After the supernova explosion, however, there would probably be a random distribution of systems reflecting the randomness in the initial orientation of the binary orbits. Since these neutron stars could have been given high peculiar velocities and were produced as long as a billion years ago, a scale height of 1 kpc is not unreasonable. Thus we conclude, admittedly with a great deal of uncertainty, that 100 such objects could currently be active within 1 kpc of the Earth. Since a critical mass of carbon will accrete every year (giving rise to the possibility of repeated bursts from the same location) the number of events with an integrated flux in the range $10^{-5}-10^{-4}$ erg cm^{-2} would be ~ 100 yr^{-1}. Even allowing for many events that go undetected this satisfies the observed frequency requirements. The large scale heights of these objects above the galactic plane would also result in a roughly isotropic distribution for the strong events. At lower energies one might begin to see some association with the galactic disk depending on the actual scale heights involved. We would predict roughly 100 events per d having total integrated flux > 10^{-7} erg cm^{-2}.

What is the fate of neutron stars that accrete at rates differing markedly from $10^{-10} M_\odot$ yr^{-1}? While there may be interesting activity associated with semi-degenerate shell flashes in such stars, we do not envision ^{12}C detonation as occurring. For a very low accretion rate, $\dot{M} < 10^{-11} M_\odot$ yr^{-1}, the energy generation rate from carbon burning is so slow that a runaway cannot occur even when nuclear energy generation exceeds neutrino losses. Electron conductivity is very efficient in such cases and using the criterion of Giannone and Weigert[17] it seems that no runaway occurs. Instead, the carbon and oxygen are neutronised at $\rho \sim 2 \times 10^{10}$ g cm^{-3}. We note, however, that a very uncertain electron screening factor has a dominant role in this statement. For much larger accretion rates, $\dot{M} > 10^{-8} M_\odot$ yr^{-1} (for the assumed geometry), the temperature of the helium-burning shell approaches 10^9K (ref. 16) so that carbon can ignite before becoming extremely degenerate and a detonation will not ensue. In this regard, the accretion rate plays a similar role to that of the mass of the star in ordinary stellar evolution. It is well known that a massive star, $M \gtrsim 10 M_\odot$, will ignite carbon in its core non-degenerately, whereas in a less massive star, carbon will ignite explosively in highly degenerate conditions[21].

Giant X-ray pulses?

We note finally the possible relationship of the above model for γ-ray burst production to the recently observed giant X-ray pulses (see discussions in ref. 22). Although the observations are difficult to interpret at this early stage we feel that two categories of X-ray bursts are being observed: aperiodic (without periodicity) and quasi-periodic. We believe, in agreement with W. D. Evans, R. D. Brian and J. P. Conner (unpublished), that the aperiodic bursts are the soft energy tails of the spectra of distant γ-ray burst sources. In the preceding section it was suggested that a plausible number of such distant

outbursts for our Galaxy was ~ 100 d⁻¹. The distribution of these bursts should correlate with the galactic plane and might have a tendency to peak towards the galactic centre where the spatial density of neutron stars is expected to be higher.

The quasi-periodic sources pose a greater problem. Periodicities as short as ~ 15 s have been observed which rule out any model based on carbon detonation. In fact, unless the neutron star can somehow act as a storage battery, a simple calculation shows that bursts with periods of ≤ 30 s and durations of 1 s cannot be seen above the steady-state accretion luminosity for any nuclear powered model. This follows from the fact that gravitational accretion liberates 10–20% of the rest mass energy of the accreted material while all subsequent nuclear reactions generate < 0.7%. Thus even if hydrogen explodes and produces X rays with 100% efficiency the 15-s observations are very difficult to interpret in terms of a flash that burns only the material accreted during the interflash period. We believe, however, that these rapid pulses can result from a series of helium (and perhaps carbon) shell flashes occurring in semi-degenerate material with a total mass ~ 10²² g that has accreted over a period of time that is long compared with the interflash period. (Admittedly, it might be difficult to accumulate 10²² g without the nuclear burning having already occurred.) The neutron star stores the potential nuclear energy for a time during which its entire output is from the release of gravitational energy and then liberates it in a series of rapid flashes. More violent flashes may heat up the material to such an extent that the diffusion of energy outwards (and hence the return to an unstable configuration) takes longer than for weaker flashes. The fact that the time between bursts is longer for the more energetic bursts is an observed attribute of certain X-ray burst sources²². Clearly a large range and diversity of nuclear outbursts

of various energies and time scales are possible for the possible spread of accretion rates, neutron star masses, and magnetic field configurations. The subject is ripe for continuing experimental investigations and serious theoretical examination, and hopefully this somewhat speculative paper will encourage both. We especially urge that known γ-ray burst sites be continuously monitored for giant X-ray pulses and vice versa.

Tritium inventories of the world oceans and their implications

Robert L. Michel

Department of Chemistry, University of California, San Diego, California 92037

Tritium inventories are given for the Pacific Ocean from 51°N to 60°S. As expected, the highest inventories are found north of 20°N. Inventories drop rapidly from 20°N to 10°N. From 10°N southwards, inventories in the top 500 m are essentially constant. From these data, it is calculated that 107±21 kg of tritium were present in the Pacific Ocean in 1970. A total of ~300±80 kg of tritium was present on the Earth's surface in 1970. This indicates that 550±160 kg of tritium have been produced by nuclear detonations. It is estimated that 62% of the tritium in the Pacific Ocean was added through molecular exchange, 5% through runoff from the continents, and 33% as precipitation.

TRITIUM ($t_i = 12.3$ yr) is present on the Earth's surface mainly as HTO. The only significant natural sources are cosmic rays passing through the Earth's atmosphere and possibly accretion from the solar wind An equilibrium quantity of ~3.5 kg is present from these sources¹. Another source of tritium is the nuclear reactor. This source has some effect on the content of atmospheric hydrogen, but accounts for only minor amounts of HTO²,³. The major source of the tritium now present on the Earth has been the detonation of fusion bombs. The amount

of tritium produced by nuclear explosions is about two orders of magnitude higher than that produced by all the other sources. Estimates of the amount have varied from 800 kg (ref. 4) to 200 kg (ref. 5).

Most tritium has been deposited in the world's oceans by one of three processes: precipitation as rain or snow, runoff from the continents, or molecular exchange. Precipitation has been monitored in detail by the International Atomic Energy Agency and continental runoff is small in comparison. The amount of tritium added through molecular exchange is not well known⁶⁻¹⁰.

The La Jolla Tritium Laboratory has studied and used tritium as an oceanographic and geochemical tracer since the late 1950s. From 1968 to 1972, several series of depth profiles from various locations in the Pacific Ocean were analysed for tritium (Fig. 1). The oceanographic implications have been discussed elsewhere¹¹, but here we use the observations to study geochemical problems such as molecular exchange and tritium inventories.

Concentrations in top 500 m of ocean

Table 1 lists inventories of tritium expressed as numbers of atoms km⁻² in the top 500 m at various profile stations. The 500-m surface layer is used. Tritium below that depth, if present in at all measurable quantities, is brought in by lateral flow

Table 1 Tritium profile inventory in the top 500 m of the Pacific

Cruise	Year	Position	Inventory $(10^{19}$ atoms km$^{-2})$
Seven Tow	1970	50°52'N 171°31'W	23.4
Seven Tow	1970	44°59'N 167°08'W	32.0

from polar latitudes and is not a result of surface input at the station.

Some profiles do not go as far as 500 m down. In some of these cases, reasonable estimates can be obtained if tritium concentrations decrease rapidly with depth. In no case should the error from these estimates exceed 10%. In some cases no estimates were possible and inventories are not given for those stations (see ref. 12 for the complete listing of data).

Correlation of data with latitude

Figure 2 shows a plot of tritium inventory against latitude. Tritium inventories are relatively constant from the subarctic Pacific to ~20°N, but further south they start to show a marked decrease. A minimum is reached at ~10°N, and throughout the Southern Hemisphere they are almost constant. Inventories are highest at northern latitudes because of the spring leak phenomenon[13], which results in a large input of tritium into the oceans from 30°N to 60°N. Oceanographic factors also affect the tritium distribution; tritium isolines and density isolines show strong correlations[11]. Density isolines start rising sharply south of 20°N and rise closest to the surface at 10°N. Tritium isolines show the same trend and a minimum in tritium inventories is found around 10°N.

Inventories for tritium below 500 m are significant only in the Southern Hemisphere. For the latitudes of 30°S to 50°S, inventories for below 500 m are approximately as large as for above 500 m (refs 12, 14). In the north, the tritium present below 500 m is negligible as a fraction of the total.

As these data cover most of the Pacific Ocean from North to South, it is possible to estimate the tritium burden of that ocean. All inventories are age corrected to 1970. The inventory is calculated assuming that the tritium inventory is constant to ±20% over a given latitude band. Only in the extreme east at 10°N does a large deviation occur. Carbon-14 values are also lower in the equatorial eastern Pacific[15] as a result of upwelling and influx of water from the South Pacific. There are two tritium profiles available from a GEOSECS station at 28.5°N (refs 16 and 17). These profiles have an average tritium inventory similar to profiles at equivalent latitudes presented here.

Michel and Suess have noted that surface tritium distributions have an east–west asymmetry with highest values in the east[11]. Also, caesium-137 determinations have shown that this

radioisotope is mixed deeper in the west and this dilutes its surface concentration[18,19], and, although vertical distributions vary, inventories seem not to be significantly different. The assumption of a constant inventory on an E–W line can be assumed to be correct within ~ ±20%.

At 28°N, one Seven Tow profile had a low inventory compared to other profiles near it. A profile taken near the same position 4 months later showed a completely different distribution, so the profile at 28°N has been deleted from calculations.

Total inventories

In Table 2, the inventories of tritium at various ranges of latitudes are given for the Pacific Ocean. The inventories include tritium below 500 m as well as in the top 500 m. It is assumed the tritium content of the deep water is negligible[16,17]. A total of 107±21 kg was found to be present in the Pacific in 1970, with > 80% of the tritium present in the North Pacific.

Table 2 Pacific Ocean tritium inventory (1970)

Latitude	Number of T atoms $(10^{19}$ km$^{-2})$	km$^2 \times 10^6$	Quantity of T (g)
< 30°N	32	30	48,000
30°N–20°N	30	14.6	21,000
20°N–10°N	15	16.6	12,500
10°N–0°	5	20.1	5,000
0°–30°S	4	49.8	10,000
30°S–50°S	5.8	26.6	7,700
< 50°S	3	19	1,900
			Total 107,000±21,000 g

Some idea of the total tritium present on the surface of the Earth can be obtained from these data and data of other researchers on tritium in other large bodies of water[14,20–23]. Most other work has been on the North Atlantic. The Atlantic north of 30°N has a consistently higher tritium inventory per square kilometre than the Pacific. South of 30°N inventories are similar. In calculating total inventories, the Atlantic is found to have an inventory 1.6 times as large as the Pacific, north of 30°N, and equal to the Pacific south of 30°N. Measurements are very sparse in the South Atlantic and inventories are assumed to be similar to those in the South Pacific at similar latitudes.

No tritium data are available from the Indian Ocean. It is assumed that inventories in the Indian Ocean are similar to those of the Pacific at similar latitudes. Most of the Indian Ocean surface area is south of the Equator where the tritium concentrations are low. Thus, the error in estimating the Indian Ocean inventory is small in terms of the total inventory. The Arctic Ocean inventory is calculated entirely on the basis of input by precipitation derived from the data of Schell and Sauzay[24]. Any input into the Arctic by molecular exchange should be small, as ice cover inhibits this process (R. Weiss, personal communication). Therefore it seems that the total tritium in the world's oceans is 250±50 kg (Table 3).

Continental tritium

A small fraction of the Earth's water supply is found in the active freshwater bodies of the continental land masses.

Table 3 World inventory of tritium (1970)

Pacific Ocean	107
Atlantic Ocean	120
Indian Ocean	20
Arctic Ocean	6
Worlds Oceans' Total	250±50 kg
Land water	45±25 kg
Air (HTO and HT)	3±11 kg
Total	300±80 kg
Fig. 1 Positions where tritium depth profiles were collected by the La Jolla Tritium Laboratory. ●, La Pared (1965); □, Scan (1969); ×, Seven Tow (1970); △, South Tow (1972); +, Eltanin (1972); O—OSN (1972).

Because of the continental effect on the tritium in rain, however, tritium concentrations are much higher in these water masses. Estimating the tritium inventory of the continental water masses is difficult, as concentrations there are much less uniform than in oceanic water masses. Also, very few data are available for 1970. It is possible to obtain an estimate of the tritium on the continents in the mid-1960s (ref. 25) which can then be age-corrected to 1970. Runoff and precipitation will cause some fluctuation in the inventory, but these effects will be small. It appears that there were 45±25 kg of tritium on the continents in 1970. The tritium content of air is known more accurately[2,3], and can be estimated to be 3±1 kg most of which is in the form HT.

Total tritium

These inventories give a total of 300±80 kg of tritium present on the surface of the Earth in 1970, most of it produced by nuclear testing.

From the world inventory, the total tritium produced by the early 1970s by nuclear explosions is calculated to be 550±160 kg,

Table 4 Modes of tritium input into the Pacific ocean (1970)

Precipitation	36 kg
Evaporation	−3 kg
Runoff	6 kg
Molecular Exchange (calculated)	68 kg
Total (from Table 2)	107 kg

where it is assumed that tritium production has been proportional to the megaton yield of nuclear explosives. Knowing the history of nuclear weapons testing, it is possible to correct for tritium decay[5].

This estimate may be low as it is assumed that no tritium is present in the deep water of the Pacific and Indian Oceans. Even a small concentration of tritium in the deep water would, however, result in a significant increase in the inventory. If the experimental upper limit of 0.2 TU (1 TU is one tritium atom per 10[18] hydrogen atoms) is used as the deep-water concentration, the figure for tritium produced by nuclear weapons testing would be 130 kg higher.

Molecular exchange

As mentioned previously, the extent of the contribution of molecular exchange to the input of tritium into the oceans is still uncertain. It was postulated[5,6] that most tritium in the oceans is added by molecular exchange. In a more formal treatment, Craig and Gordon[7] came to essentially the same conclusion. This seemed, however, not to be in agreement with experimental data. Two ocean studies[8,9] found experimentally that molecular exchange added < 0.33 of the tritium present. But the measurements were carried out in areas of low humidity where molecular exchange is expected to be low. Simpson[10] also found that molecular exchange could account for only about one third of the tritium added to Crater Lake. Conditions for this lake, however, are substantially different from those prevailing over the oceans, and the results are not necessarily significant for this problem.

Our data can be used to calculate the large scale molecular exchange for the Pacific Ocean. The only functions which affect tritium inventory are precipitation (P), evaporation (E), decay, runoff (R) and molecular exchange (ME). With the data corrected for decay, input by molecular exchange can be found by

$$ME = I - P - R + E \qquad (1)$$

where I is the inventory in 1970 (107 kg).

The amount of tritium deposited in the Pacific since 1963 can be calculated from the data of Schell and Sauzay[24]. Rainfall for most of the North Pacific is taken from data compiled by Reed and Elliott[26]. Rainfall data south of 20°N and evaporation data are taken from Sverdrup et al.[27]. Tritium concentrations at the sea surface are well known in the Pacific[12,13] so evaporation loss can be evaluated. The relative amounts of tritium added before 1967 have been calculated by Roether[11]. These data combined with the input data of Schell and Sauzay[24] have been used to estimate the input before 1963. All input by precipitation was corrected to establish the tritium deposited by 1970, and the net input was found to be 33 kg.

Approximately 9×10^{15} l of water enter the Pacific Ocean each year as runoff. Estimates of the tritium content of runoff are available from International Atomic Energy Agency (IAEA) data[28]. In calculating total runoff, it is assumed that runoff is of equal volume in all latitude bands from 50°N to 50°S. In

Fig. 2 Inventory of tritium in the top 500 m of the Pacific Ocean km[-2]. Symbols as for Fig. 1.
latitudes where no tritium data are available, it is expected that variations in tritium concentration in runoff are similar to the variations in rainfall. The errors are large but runoff tritium is small compared to input by molecular exchange or precipitation, being responsible for ~ 6 kg of the 1970 inventory. The input by molecular exchange is then found to be 68 kg (Table 4). This is 62% of the total tritium input in the Pacific—in agreement with previous estimates—and almost twice the input by precipitation alone. Thus, molecular exchange is indeed the predominant mechanism by which tritium enters the oceans.

This work was supported by the Chemical Oceanography Division of the NSF. Karen Dockins was in charge of technical operations of the La Jolla Tritium Laboratory until 1971, and then Teresa Broadwell took over. We thank H. E. Suess for discussions.

Rolling hairpin model for replication of parvovirus and linear chromosomal DNA

A novel, quasicircular scheme is proposed for the replication of parvovirus DNA. Daughter strands are initiated after the copying and rearrangement of a terminal palindromic sequence, a process termed 'hairpin transfer'. Such a process may be involved in the replication of other viruses and host cell DNA.

ALL known DNA polymerases require a 3'-OH terminus on which to initiate strand elongation[1-3]. Although a satisfactory mechanism for the complete replication of circular DNA molecules can be envisaged by using RNA primers[3], additional molecular conjuring is required to explain the completion of the 5' termini of daughter strands in a linear DNA molecule. The problem arises because excision of a terminal RNA primer leaves a 5' terminal gap and because no polymerase is known which catalyses DNA chain growth in a 3' → 5' direction. Several elegant models have been put forward to circumvent the difficulty, all requiring special terminal structures, for example, terminal redundancy[4], palindromic termini[5] and covalently continuous (cross-linked) termini[6]. It has not been feasible to determine whether such terminal structures exist in the DNA molecules of eukaryotic cells, because of their extremely high molecular weight[7]. But practicable model systems for the study of chromosome structure and replication are provided by animal viruses with linear DNA genomes. For example, the parvoviruses contain linear single-stranded DNA genomes of only 1.4×10⁶–1.7×10⁶ daltons[8,9], which replicate

by way of linear double-stranded intermediates[10-18]. They are divided into two subgroups. The members of one subgroup, the adeno-associated viruses (AAV), are entirely dependent on adenovirus coinfection for their own replication, and package both plus and minus DNA strands in separate virions[8,9]. Members of the other subgroup, the autonomous parvoviruses, can replicate without a helper virus and package a unique viral DNA strand[8].

Structure of the parvovirus genome

To determine whether special arrangements of nucleotide sequence are necessary for the replication of a linear DNA molecule, we have examined the structure of the genome of the minute virus of mice[19] (MVM), an autonomous parvovirus. The results of this study[20] are summarised in Fig. 1. We have shown[20] that the 5' end of the molecule is a hairpin, represented diagrammatically by the sequence ABa. The duplex Aa can be isolated as an S1 nuclease-resistant, hydrogen-bonded fragment about 130 base pairs long, containing the 5' terminal base. The sequence represented by D is about 95% of the total genome. It is entirely single stranded and approximately 4,100 bases long. The 3' end can also form a hairpin denoted EFe, which serves as a primer for the synthesis of the complementary strand *in vitro* by a number of DNA polymerases. Various oncornavirus DNA polymerases (reverse transcriptases) can use MVM DNA efficiently as a primer-template. Since these polymerases lack exonuclease activity[21,22] and require base-paired primers[21-23], this implies that the 3' terminal base is hydrogen bonded in the duplex Ee. The length of this duplex is not precisely known, but it does not seem to be stable at

37 °C *in vitro*, as the entire genome, excluding the 5' hairpin, is sensitive to *E. coli* exo I (ref. 20). In addition, its priming ability is not destroyed after treatment with *E. coli* exo III.

Polymerases lacking 5' to 3' exonuclease activity synthesise a duplex DNA with a molecular weight 1.96 times that of the viral genome, in which the complementary strand is covalently attached to the template[29]. Restriction enzyme cleavage of this duplex has established that the viral genome is not circularly permuted[29]. The sizes of the single-stranded loops (B and F) are not known exactly, but they are less than 100 bases long, since they cannot be detected by electron microscopy. The observation that the loop F in the MVM duplex synthesised *in vitro* is extremely resistant to cleavage by S1 nuclease (D. C. W. unpublished results) suggests that this loop may be very small.

The structure determined for MVM DNA as shown in Fig. 1 has been demonstrated for several parvovirus genomes (M. B. Chow and D. C. W., to be published), and leads us to propose a model for the replication of such molecules. We have called this scheme the rolling hairpin as it is quasicircular and, in some respects, resembles the rolling circle model proposed for coliphage ΦX174 DNA replication by Gilbert and Dressler[34].

Rolling hairpin

The first step proposed for parvovirus DNA replication, shown in Fig. 2, is the gap-fill synthesis of the complement d of sequence D; as mentioned above, this step can be performed *in vitro* by several DNA polymerases[20]. This is followed by displacement synthesis and gap-fill synthesis, to copy the 5' terminal hairpin sequence aBA. To continue synthesis, we propose that this terminal duplex palindrome is now rearranged to form the 'rabbit-eared' structure shown in Fig. 2iv. This terminal synthesis and rearrangement recreates the hairpin originally present at the 5' end of the parental genome. At the
Fig. 1 Structure of MVM genome. In this and subsequent Figs, letters are used to represent unique blocks of sequence. The upper and lower cases denote complementary sequences, that is, if A is 5'-A-T-G-G-C-A-C-3' then a would be 5'-G-T-G-C-C-A-T-3'. The arrow denotes the 3'-OH end of a strand.

same time, it creates a copy of this hairpin, on the 3' end of the complementary strand, which can serve as a primer for the synthesis of the progeny strand. The new 3' hairpin eventually becomes the 5' hairpin of that future progeny genome, as shown in Fig. 2v. This process of 'hairpin transfer' is the essence of the model. The dimer length duplex is then completed by displacement synthesis. The resulting molecule comprises a single polynucleotide chain from which two viral genomes could be generated by suitable endonucleases; that is, the scheme shown in Fig. 2 represents one genome duplication. In the absence of endonuclease cleavage, however, this structure is obviously capable of continued synthesis by the same mechanism, yielding larger and larger multimers. In this respect our model strongly resembles the rolling circle model[34]. Thus a further roll around the 5' hairpin (that is, a repeat of steps *ii* to *vi* in Fig. 2) would generate the tetramer as shown in Fig. 3. In the concatemers formed by this replication process, the viral genomes are situated alternately on opposite strands of the duplex, with their palindromic ends overlapping.

If the single-stranded loop sequences B and F are themselves palindromes, with a phosphodiester bond as the axis of
Fig. 2 The rolling hairpin model for parvovirus replicative DNA synthesis. *i*, Gap-fill synthesis; *ii*, displacement synthesis and *iii*, gap-fill synthesis to complete genomic hairpin; *iv*, enzymatic rearrangement of terminal palindrome to give rabbit-eared structure; *v*, displacement synthesis and *vi*, gap-fill synthesis The molecule is now essentially the same structure as the first intermediate between steps (*i*) and (*ii*), and repetition of steps (*ii*) and (*iii*) generates the dimer genomic hairpin. Repetition of steps (*iv*), (*v*) and (*vi*) generate the tetramer, and so on for larger multimers.

rotational symmetry (for example, GGTACC), there would be no difference between sequences B and b or between sequences F and f, and all genomes would be exactly the same; if they are not palindromes, then there would be four different kinds of viral sequence which differed in two small regions.

So far we have described a scheme for generating and replicating duplex forms of parvovirus DNA, based on the structure of the genome. The model now allows an explanation of some hitherto puzzling physical properties of parvovirus replicative intermediates. We showed previously[10] that some of the MVM duplex DNA molecules found in infected cells seemed to be concatemers up to about ten genome equivalents long. These molecules, however, contained no single strands longer than two genome equivalents, and on denaturation and reannealing formed predominantly monomer length duplexes. The long duplexes were also reduced to approximately monomer length by heating to submelting temperature. In addition we found that a large fraction of the MVM double-stranded DNA reannealed in a monomolecular fashion after denaturation, suggesting that viral and complementary strands were linked covalently, as predicted by the rolling hairpin model. Similar spontaneous renaturation behaviour has since been reported for duplex intermediates of parvovirus X 14 (ref. 14), AAV-2 (ref. 15) and Kilham rat virus[16]. Recently Straus *et al.*[16], have reported the isolation, from AAV-infected cells, of dimer length duplexes which renature spontaneously. These comprise a single DNA chain, four genomes long, containing alternating viral plus and minus strands. They have proposed a model for the replication of AAV DNA involving hairpin primers which is similar in parts to that proposed in Fig. 2. We originally suggested[10] that hairpin duplexes of genome length were formed by the use of the 3' end of the viral strand as a primer for the

synthesis of its complementary strand, and that this implied a mechanism for the regeneration of the primer in order to preserve the entire base sequence of the genome during replication. In the rolling hairpin model, this is accomplished by the process of hairpin transfer.

The overall physical properties of double-stranded DNA molecules replicating according to the model, such as the lengths of the single strands which the duplexes contain and the proportion of spontaneously renaturing molecules, will depend on how the intermediates are further processed to generate progeny genomes.

Synthesis and packaging of progeny viral DNA

A replication scheme which generates concatemers as replicative intermediates must necessarily include some process for excising progeny viral DNA. In parvovirus replication it is unlikely that this process relies only on the selection of genome size segments, since the viral DNA is not circularly permuted[20,26]. We envisage the first step in the process to be the introduction of a single-strand break, at the 5′ end of a genome within the

Fig. 3 Proposed mechanism for parvovirus progeny DNA synthesis, showing a tetramer intermediate. The progeny DNA strand, V, is indicated throughout as the heavy line. d represents the ~4,100 nucleotides of the complementary strand which is not packaged by the autonomous parvoviruses. The circle represents the capsid of an immature virion. *i*, Internal initiation of progeny strand displacement by sequence-specific nuclease cleavage; *ii*, displacement of progeny strand by elongation using the 3′-OH of the 'nick' as primer, and driven by concomitant packaging; *iii*, packaging of complete genome, and cleavage of 3′-OH end of genome (arrow); *iv*, release of intact virion and repair of the 3′ end of newly synthesised progeny strand to the 5′ end of its adjoining complementary strand; *v*, completion of a mature virion in the opposite direction and regeneration of the initial tetramer.

concatemer, that is between d and A in Fig. 3*i*. The 3′-OH terminus at this nick is then used as a primer for displacement synthesis of progeny DNA strands, giving rise to the duplex molecules with single-stranded side chains that are observed in infected cells[10,13,17]. In addition, we suggest that this displacement synthesis is driven by concomitant packaging of the progeny strand because little, if any, free single-stranded DNA can be detected during infection[13,14,17,18]. This idea is supported by the report[20] that a temperature-sensitive mutant of H-1 virus, with a virion which is physically unstable at high temperature, makes replicative intermediate, but not progeny DNA, at the non-permissive temperature.

After the 3′ terminal sequence e has been displaced, excision of the progeny genome could be completed by another sequence-specific nuclease, perhaps an integral part of the virion, releasing an intact virus particle and stopping the displacement synthesis. This second nuclease must be inactive on double-stranded DNA, because otherwise it would also introduce a nick in the template strand. The nascent 3′ OH terminal sequence e must be rapidly rejoined to the existing sequence d because the intact strand may be required as a template for the 3′ terminus of another genome being synthesised in the opposite direction, as in Fig. 3*iv*. If the packaging of progeny strands drives the displacement synthesis, the continued synthesis of complementary, minus strands (sequence d) is avoided, and the asymmetrical synthesis of progeny genomes, which has been reported for the autonomous parvoviruses[10,13,17] is assured. The specificity of such a packaging mechanism implies recognition of the 5′ end of the genome by the precursor virion. It is interesting that when infectious particles of MVM are lysed gently and examined in the electron microscope, a significant number of capsids remains associated with an end of the extruded DNA[30]. There is no detectable relationship between the two ends of MVM DNA[30], whereas the ends of most AAV genomes are related by an inverted terminal redundancy[27,28]. If terminal sequence recognition by the particle controls strand selection, this could explain why MVM only packages the plus strand, whereas AAV packages both plus and minus strands.

In concatemers where the 5′ ends of overlapping genomes have been nicked, displacement synthesis at one or both nicks will break the molecule in this region. Subsequent synthesis would regenerate the terminal palindrome of each of the fragments, which would then be able to continue replication after rearrangement as described in Fig. 2*iv*. Since none of the strands in double-stranded MVM DNA was found to be greater than dimer length[10], we suggest that the duplex concatemers had been nicked, perhaps during isolation, at the 5′ end of every component genome. Each continuous strand in such a molecule would have the sequence ABaDEFed and therefore comprise two palindromes. These sequences could rearrange, through cruciform intermediates, to produce monomer length hairpin duplexes at elevated temperature. This could explain the breakdown of MVM concatemers to monomers when they are heated to subdenaturing temperatures[10]. As both palindromic sequences in the concatemer would, in effect, become terminal hairpins in the monomer, one would expect this process to be essentially irreversible.

Hairpin transfer process

The central process of the rolling hairpin model is the synthesis and rearrangement of the palindromic terminus, to produce a 'rabbit-eared' structure. This permits the direction of chain growth to be reversed with respect to the original duplex. The rearrangement need not require complete melting out of the terminal region. If the loop sequence B is short it would be possible to interconvert the two structures through a cruciform intermediate, originally described by Platt[29] as twist transfer. Maniloff[30] has suggested, on theoretical grounds, that such a rearrangement should exhibit a transitional energy barrier and would be unlikely to occur spontaneously in physiological conditions. Therefore we have to postulate that there is an

Fig. 4 Proposed model for eukaryote chromosome terminal replication. *i*, Enzymatic rearrangement of terminal palindrome; *ii*, strand-displacement synthesis of daughter strand using 3'-OH of the parental strand as primer; *iii*, sequence-specific nuclease cleavage followed by *iv*, strand displacement and *v*, gap-fill synthesis to regenerate terminal palindrome.

enzyme activity which catalyses the rearrangement, and suggest that it is part of the DNA replication system of the cell which parvoviruses and possibly other viruses, require for rearrangement of their chromosomal ends during replication.

Hairpin transfer and host cell replication

To overcome the problem of replicating termini, originally discussed by Watson[4], Cavalier-Smith suggested[5] that the ends of linear chromosomes are palindromic so that, after excision of the 5'-terminal RNA primer, the exposed DNA strand could form a 3'-OH terminated hairpin. He proposed that this is then joined to the 5' end of the complementary strand by gap-fill synthesis and ligation. The palindromic sequence is then nicked at its 5' end by a sequence-specific nuclease. A combination of strand displacement and gap-fill synthesis, using the 3'-OH of the nick as primer, reconstitutes the parental strand.

Based on studies with MVM we have proposed a model for the replication of the parvovirus genome which overcomes the problem of the completion of linear termini by the process we have described as hairpin transfer. This concept can be extended to the replication of host chromosomes and other linear DNA molecules, and thus becomes a modification of Cavalier-Smith's model, involving fewer separate steps. In this scheme (Fig. 4), the steps of strand separation, RNA primer synthesis, excision, hairpin formation, repair synthesis and ligation, are replaced by the enzymatic rearrangement of the terminal palindrome. This produces a 'rabbit-eared' structure whose 3' end acts as a primer for the synthesis of the complementary strand. A sequence-specific nuclease then nicks at the 5' end of the palindrome, and synthesis using the 3'-OH of the nick as primer, reconstitutes the terminal sequence as before.

It is reasonable to expect that the expression of an enzyme system responsible for the initiation and completion of replication at chromosome termini would be coordinated with the passage of the cell through the mitotic cycle; in this respect it is important that the autonomous parvoviruses depend on, but cannot induce some host function(s) expressed transiently in the S phase[6]. The limited genetic capacity of these viruses suggests that they alter the host cell replication machinery very little. We suggest that the parvoviruses usurp the host's system for duplicating the termini of its chromosomes, to replicate their own DNA by the rolling hairpin process.

Terminal palindromes, which form terminal hairpins on strand separation, are emerging as a common feature of linear chromosomes. In addition to MVM DNA[20], such sequence arrangements have been demonstrated in the genomes of AAV[21] and herpesvirus[22]. The covalently continuous structure demonstrated for the vaccinia virus genome[23] could be regarded as a special form of terminal palindrome. These palindromes are found irrespective of the existence or polarity of terminally redundant regions in such molecules, either inverted as in adenovirus DNA[24,25], non-inverted as in herpesvirus DNA[22,34], or a mixture of both as found for populations of AAV DNA molecules[9,17,18,37].

Studies showing that a combination of exonuclease, polymerase and ligase can cross link the ends of coliphage T7 DNA[28,39] indicate that the T7 genome similarly contains a terminal palindrome, which agrees with the observation[40] that the termini of T7 DNA contain a self-complementary sequence. The isolation, from T7-infected cells, of spontaneously renaturing intermediates of greater than genome length[41] suggests that this sequence might be used for the replication of T7 termini also. Terminal palindromes may, therefore, be necessary for the replication of all linear chromosomes which do not, like phages λ or T4, replicate by becoming circular.

We thank Drs G. J. Bourguignon, L. Enquist and A. J. Shatkin for useful discussion and Drs J. Cairns and C. M. Radding for criticism of the manuscript.

Relationships between structure and activity of retinoids

Michael B. Sporn, Nancy M. Dunlop, Dianne L. Newton & William R. Henderson

Lung Cancer Branch, Carcinogenesis Program, National Cancer Institute, Bethesda, Maryland 20014

Structure–function relationships of 19 retinoids were studied in three in vitro systems in defined, serum-free medium. These systems measure effects on differentiation and growth, as well as toxic effects. The ring, side chain, and polar terminal group of natural retinoids all may be modified synthetically to yield highly active compounds. Several retinoid ethers were found to be significantly less toxic than the corresponding carboxylic acids or alcohols.

RETINOIDS (the set of molecules comprised of vitamin A and its synthetic analogues) are known to exert profound effects in controlling cellular differentiation in epithelium of many target tissues, including bronchi and trachea, uterus, prostate, kidney and bladder, stomach, intestine, pancreatic ducts, and skin[1]. It has recently been shown that several synthetic retinoids can prevent the development of epithelial cancer of the skin[2,3], respiratory tract[4], mammary gland[5,6], and urinary bladder[7] in experimental animals. In these experiments, the retinoids were not given to the animals until after completion of administration of the respective carcinogens. In these conditions, the retinoids do not prevent initiation of carcinogenesis, but rather, they modify preneoplastic states during the latent period of cancer development, before the onset of invasive malignancy. Although retinoids may act by more than one mechanism to modify preneoplastic states, their direct ability to control cell differentiation in target epithelia is undoubtedly of major importance in their suppression of carcinogenesis. For example, it has been shown that direct application of retinoids to prostatic[7,8] and tracheal[9] organ cultures can reverse hyperplastic or anaplastic lesions induced by chemical carcinogens; in these experiments, also, retinoids were not added to the cultures until after the lesions had been initiated by the carcinogen.

Many synthetic retinoids have now been made, in which there has been substantial modification of the ring, side chain, or polar terminal group of the natural vitamin A molecule. For both practical and theoretical considerations, an analysis of structure–activity relationships in this set of molecules is of fundamental importance. It is important to establish not only the molecular parameters that are required for retinoids to control epithelial cell differentiation and to prevent carcinogenesis, but also to establish the molecular parameters responsible for the undesirable toxic effects which retinoids may have on tissues, since such toxic effects may limit the effective use of retinoids in cancer prevention[10]. It is already clear that several synthetic retinoids, which have potent activity for the prevention of cancer in experimental animals, for the control of epithelial cell differentiation *in vitro*, or for reversal of premalignant lesions *in vitro*, have little capacity to promote growth in animals maintained on vitamin A-deficient diets[11]. Thus, classical nutritional methods (promotion of growth in vitamin A-deficient animals) may not be particularly useful to assess the potential activity of retinoids in cancer prevention, and new methods must be developed for correlation of structure and activity. Although measurement of ability to prevent various types of epithelial cancer in the intact experimental

animal is an important measure, such tests are very expensive and time-consuming when assaying large numbers of new compounds. Moreover, it is difficult to evaluate cellular and biochemical mechanisms of action in the live animal.

For these reasons, we have assayed the activity of retinoids in several organ and cell culture systems, using chemically defined, serum-free medium, in which structure–activity relationships can be evaluated quantitatively. Here we report on the biological activity of 19 retinoids in three such *in vitro* systems, which measure effects on both cell differentiation and growth (reversal of keratinisation in retinoid-deficient tracheal epithelium, increase of RNA in epidermal cell cultures), as well as the toxic effects on tissue (destruction of tracheal cartilage). More than 5,500 organ and cell cultures (including untreated control cultures) were used in these assays. Finally, since it is important that *in vitro* measurements be extended to evaluate utility *in vivo*, we also describe some major *in vivo* changes in tissue distribution of retinoids which result from synthetic modification of the polar terminal group.

Methods for *in vitro* studies

Structures of the retinoids (all provided by Hoffmann–La Roche Inc., Nutley, New Jersey and F. Hoffmann–La Roche & Co. A. G., Basel, Switzerland) used in the present study are shown in Fig. 1 and Table 1. Three series of retinoids have been studied: Fig. 1*a* retinoids which retain the β-cyclohexenyl ring and the all-*trans* side chain of the natural retinoids, but which have modifications of the polar terminal group; Fig. 1*b* retinoids in which a fluorine atom has been inserted into the all-*trans* side chain; and Fig. 1*c* retinoids which have a substituted

ED50(M) for reversal of keratinisation in tracheal organ culture is the dose for reversal of keratinisation in epithelium of 50% of retinoid-deficient hamster tracheas using standard assay conditions[13]. ED50(M) for increase in RNA in epidermal cell culture is the dose for 50% increase in total RNA in mouse epidermal cells, also using standard assay conditions[14]. TD50(M) for toxicity to cartilage in tracheal organ culture is the dose for release of 20% of total proteoglycan from hamster tracheal cartilage into culture medium using standard assay conditions (see text).
*Numbers of organ or cell cultures used for evaluating each retinoid are shown in parentheses.

aromatic (trimethylmethoxyphenyl, TMMP) ring, as well as modifications of the polar terminal group. All retinoids were dissolved in dimethylsulphoxide (DMSO) before addition to cultures; an equivalent amount of DMSO (which never exceeded 1%) was added to all control cultures.

The test systems both for assay of reversal of keratinisation in organ cultures of tracheal epithelium from retinoid-deficient hamsters[12,13], and for assay of increase in RNA in cell cultures of mouse epidermis[14], have been described in detail. Typical dose–response curves for effects of retinoids in reversing keratinisation in tracheal organ culture are shown in Fig. 2; typical dose–response curves of their effects in increasing RNA in epidermal cell cultures have been published previously[13]. Toxicity of retinoids to cartilage of hamster trachea in organ culture was measured by a modification of a procedure for assay of retinoid toxicity to rabbit ear cartilage[11]. Briefly, tracheae from 4–5-week-old hamsters fed a normal laboratory stock diet were removed in sterile conditions, trimmed carefully of connective tissue, and then cultured for 3 d in the same medium used for the assay of keratinisation reversal, using air containing 5% CO2 as the gas phase. These tracheal organ

cultures were exposed to retinoids during the entire 3-d period Crystalline bovine serum albumin (0.5%) was added to some cultures to ensure solubility of retinoids at the highest concentrations used. After this period, both the trachea and the culture medium from each dish were saved; the amount of cartilage proteoglycan released into the culture medium, as well as that remaining in the cartilage, was measured with Alcian blue[15]. The total proteoglycan remaining in the cartilage was solubilised by papain digestion (digestions were performed at 37 °C for 2 h with shaking, using crystalline papain, 1 mg ml^{-1}, in 0.05 M sodium acetate buffer, pH 5.8, containing 0.001 M cysteine HCl). Chondroitin sulphate was used as the proteoglycan standard. At the end of the assay, the amount of proteoglycan found in the culture medium and the amount remaining in the cartilage were summed, and toxicity for any retinoid at any dose level was plotted (Fig. 3) as the percentage of the total proteoglycan released into the medium[11].

Reversal of keratinisation by retinoids

The ability of the respective retinoids to suppress keratinisation and reverse squamous metaplastic lesions caused by retinoid

Table 2 Comparison of tissue levels of retinoids 24 h after either a single or the last of nine oral doses

Retinoid	Single dose			Nine doses		
	Number of rats	Liver	Breast	Number of rats	Liver	Breast
Solvent control	18	0.37±0.02	0.0052±0.0003	19	0.53±0.02	0.0088±0.0015
Retinyl acetate	18	1.82±0.13	0.014±0.002	17	11.80±0.75	0.082±0.004
Retinyl methyl ether	17	0.92±0.10	0.060±0.01	10	7.38±0.98	0.71±0.10
Retinyl butyl ether	12	0.45±0.04	0.026±0.004	12	0.79±0.03	0.10±0.01

Sprague–Dawley female rats were dosed orally with retinoids (30 μmol each dose) dissolved in 0.4 ml of ethanol–trioctanoin (1:3). The rats receiving nine doses were treated three times weekly. All rats were killed 24 h after their final dose and tissue levels were determined with the trifluoroacetic acid method[37] after extraction of tissue with ethyl ether[36]. Retinyl acetate, retinyl methyl ether, and retinyl butyl ether all gave linear standard reactions with trifluoroacetic acid at 616 nm. Figures are total μmol of retinoid found per g wet weight tissue ± standard error.

deficiency in tracheal epithelium is shown in Table 1 and Fig. 2. This assay is a very sensitive measure of the ability of retinoids to control normal epithelial cell differentiation, since the same process can be shown to occur in the live animal[1]. Dose–response plots (Fig. 2) were made for all retinoids, and the values derived for the dose effective in suppressing keratinisation in half the cultures are shown in Table 1. Many retinoids were extremely active in the 10^{-9} M range (approximately 300 pg ml^{-1}).
Fig. 2 Dose–response curves for reversal of keratinisation in organ cultures of retinoid-deficient tracheal epithelium by application of retinoids. Tracheae (one per culture dish) were treated with retinoids for 7 d before scoring for the presence of both keratin and keratohyaline granules. ▲, Retinoic acid; △, retinyl acetate; ●, N-acetyl retinyl amine; ○, N-retinyl phthalimide. Similar curves were obtained for all retinoids reported in Table 1, and the ED$_{50}$ was derived from these plots. Numbers of tracheae used in these experiments are shown in Table 1.

Several interesting results can be seen. In both series of retinoids—those with a β-cyclohexenyl ring (Fig. 1a), as well as those with an aromatic TMMP ring (Fig. 1c)—compounds with a carboxylic acid terminus were slightly more active than those with a carboxylic acid ethyl ester or carboxylic acid ethyl amide terminus, although the differences were not great. Also, in both series, compounds with terminal methyl ether functions were almost as active as the corresponding alcohols. Retinyl butyl ether was one-tenth as active as retinyl methyl ether or retinyl acetate. The oxygen atom on the terminal carbon of retinyl acetate may be replaced with an amine function, resulting in the compound N-acetyl retinyl amine, which was one-third as active as retinyl acetate. The N-phthalimide derivative was essentially inactive, except at the highest concentration tested. The acetylhydrazone derivative of retinal was almost as active as the parent aldehyde, although the oxime derivative of retinal had much less activity. The 12- and 14-fluoro-derivatives of retinoic acid ethyl ester were very active in reversing keratinisation.

RNA increase in epidermal cultures by retinoids

The ability of the respective retinoids to increase RNA in epidermal cell cultures is also shown in Table 1. There is a remarkable correspondence between activities as measured in the tracheal organ culture assay and the epidermal cell culture assay for 15 of the 19 retinoids. Three retinoids (retinyl butyl ether, N-acetyl retinyl amine, and retinoic acid ethyl amide) which reverse keratinisation in tracheal epithelium, were essentially inactive in the epidermal cell culture system, and a fourth compound, 12-fluororetinoic acid ethyl ester, was markedly less active in the epidermal cell assay. The reason for the above four exceptions is not known; but it is conceivable that epidermal cells from newborn mouse skin are deficient in the appropriate enzymes which might activate these four retinoids to biologically active forms in tracheal epithelium.

Toxicity of retinoids to tracheal cartilage

The toxicity of retinoids to tracheal cartilage *in vitro* is shown in Table 1 and Fig. 3. Dose–response plots (Fig. 3) were made for all retinoids, and the values derived for the dose that would release 20% of the total tracheal proteoglycan are shown in Table 1. Retinoic acid, retinoic acid ethyl ester, 12- and 14-fluororetinoic acid ethyl ester, the TMMP analogue of retinoic acid, and the TMMP analogue of retinoic acid ethyl ester were the six most toxic compounds. In both series of retinoids (Fig. 1a, c), the ethyl amide derivatives were markedly less toxic than their respective parent carboxylic acids. Similarly, the methyl ether derivatives were significantly less toxic than their respective parent alcohols, which in turn, were less toxic than the corresponding carboxylic acids. Two compounds, namely retinyl butyl ether and N-acetyl retinyl amine, which could control tracheal epithelial cell differentiation *in vitro* were virtually without toxicity to tracheal cartilage *in vitro*. These two compounds were also essentially inactive in the epidermal cell culture assay. All these data suggest that metabolic activation of retinyl butyl ether and N-acetyl retinyl amine may be required for their activity, and that, in some circumstances, there may even be a different set of metabolites which control cellular differentiation and cause cellular toxicity.

Pharmacokinetics of retinoids

The above *in vitro* studies clearly show a wide range of changes in activity resulting from modification of the structure of the retinoid molecule. Practical usefulness of retinoids for cancer prevention depends not only on a compound having the desired activity and lack of toxicity, but also on its pharmacokinetics *in vivo*. Thus, although retinyl acetate is highly active and relatively non-toxic (compared with retinoic acid) *in vitro*, it has the undesirable property *in vivo* of being stored in the liver, mostly as retinyl palmitate[16,17]. These elevated levels of retinyl palmitate can eventually cause serious toxic effects, both in the liver and systemically[17]. Moreover, because of the tendency of retinol and its esters to be stored in the liver, these retinoids may not reach specific target organs in doses as high as might be desired.

The greater effectiveness of retinyl methyl ether, compared with retinyl acetate, in prevention of mammary cancer in rats has recently been reported[6]. One possible explanation of these findings might be that greater effective levels of retinyl methyl ether than of retinyl acetate were attained in the mammary gland, so we carried out experiments to investigate this possibility. High doses of retinoids, corresponding to those used previously[6] when prevention of mammary cancer was investigated, were given in these experiments. After either single or multiple oral dosing of retinyl methyl ether, much greater levels of this compound (or one of its metabolites which react positively with trifluoroacetic acid, TFA) were indeed found in the mammary gland and adjacent fat pad, than after similar dosing with retinyl acetate (Table 2). Retinyl methyl ether *in vivo*, however, is known to be cleaved to retinol and then to be stored in the liver as retinyl ester[16,18]; results shown in Table 2 confirm this known ability of the liver to store large amounts of retinyl methyl ether or its metabolites. Thus, although retinyl methyl ether yields high retinoid levels in the mammary gland and adjacent fat pad, the storage of this compound and its metabolites in the liver suggests that, if retinyl methyl ether is fed for long periods, it may be as potentially toxic to the liver as retinol or retinyl esters.
Fig. 3 Dose–response curves for toxic effects of retinoids to tracheal cartilage in organ culture. Tracheae (one per culture dish) were treated with retinoids for 3 d before measuring both proteoglycan released into the culture medium, and that remaining in the cartilage. ▲, Retinoic acid; △, retinyl acetate; ●, *N*-acetyl retinyl amine. s.e.m. of measurements is shown. Numbers of tracheae used in these experiments are shown in Table 1.

In contrast, another retinoid ether, retinyl butyl ether, seems to be metabolised by the intact animal in an entirely different way from retinyl methyl ether (Table 2). In spite of the fact that multiple dosing of retinyl butyl ether caused a twelvefold increase in the amount of TFA-positive retinoid in the breast, it did not even cause a twofold increase in liver retinoid in these experiments; in contrast, retinyl acetate and retinyl methyl ether respectively caused 22-fold and 14-fold increases in liver retinoid levels. The data indicate a major difference between the metabolism of retinyl butyl ether and of retinyl methyl ether, which we are now investigating using liver microsomes *in vitro*. Retinyl butyl ether thus seems to have the following unusual cluster of properties: it is a derivative of retinol with very low direct toxicity to tissue; it has significant growth-promoting activity in the whole animal[30]; and it does not accumulate in the liver after repeated oral dosing at high levels.

Conclusions

The data presented above show the complexity of relationships between structure and activity in retinoids. Significant modifications have been made in all three regions (ring, side chain,

and polar terminus) of the retinoid molecule and these modifications have resulted in biologically active molecules that may have practical use. Although it would not be justified to generalise to other retinoids from the present data, the following conclusions may be drawn from the present studies on retinoids with β-cyclohexenyl and TMMP rings: (1) the presence of a terminal carboxylic acid function conveys high activity, but is also associated with high toxicity; (2) fluorine atoms may be inserted into the side chain of β-cyclohexenyl retinoids to yield highly active compounds, of which the pharmacokinetics are at present largely unknown; (3) a terminal amine function, as in *N*-acetyl retinyl amine, is compatible with activity and may result in an analogue with low direct toxicity to tissue; and (4) modification of the polar terminal group can markedly lessen toxicity, and as shown with retinyl methyl ether and retinyl butyl ether, may also usefully affect pharmacokinetic properties.

The present data yield little information about the 'active form' of retinoids. A variety of retinoid structures are now known to be active in control of cell differentiation. The recent description and purification of several retinoid-binding proteins[31-36], which may have some resemblance to steroid-binding proteins, suggest that there need not be a single active form of retinoids. Rather, a wide range of retinoid structures may interact with cellular receptors directly in a biologically significant manner.

Do superheavy elements imply the existence of black holes?

THE discovery[1] of the superheavy elements 116, 124, and 126 raises the question of where these elements are likely to have been formed. The majority of the post-iron-peak nuclei are thought to have been produced in conditions of explosive nucleosynthesis (the r-process), particularly in conventional supernova explosions. The ability of the r-process to produce superheavy elements is, however, very uncertain[1]. The conditions necessary for superheavy element synthesis (β-decays occurring sufficiently slow that the $n \gamma \leftrightarrows \gamma n$ equilibrium is not disturbed) are difficult to realise in astrophysical situations. The n-process (J. B. Blake and D. N. Schramm, unpublished) requires less extreme conditions (the β decays are important) and may occur more often. The majority of the elements normally attributed to the r-process may have been synthesised in this way. Neutron-induced fission causes both processes to terminate at nuclei with high proton numbers, Z, but the n-process may allow it to reach the higher Z value.

We note that superheavy elements, such as those discovered and others much less stable in our environment, must exist in the outer layers of a neutron star[2]. Moreover, ideal conditions for the production of superheavy nuclei (high neutron flux and rapid β decays) are found in the disruption of a neutron star. The β decay rate is then fast compared with the expansion time scale (ref. 4 and J. M. Lattimer and D. N. Schramm, unpublished). We envisage such disruption being possible in either of two ways, both of which involve a black hole. Lattimer and Schramm (unpublished) and Lattimer *et al.*[4] have considered the tidal disruption of a neutron star from a close encounter with a black hole. Most of the disrupted star is swallowed by the hole, but some of the processed stellar material is assumed to escape.

Perhaps a more likely situation in which a neutron star is disrupted occurs when it accretes sufficient material that its mass exceeds the maximum mass for stable neutron stars. It has no alternative other than to collapse to form a black hole, and it again seems plausible that some of the outer layers are thrown off as it does so. The binary X-ray sources such as Her X-1 and Cen X-3 provide evidence that accreting neutron stars do exist.

The accretion process is enhanced if such binary systems tend to evolve towards coalescence, as is expected. One product of such evolution could be the giant stars envisaged by Thorne and Zytkow[4], in which accretion on to a neutron star core is a major power source for the whole star. Assuming that the neutron star cannot accept material at a rate much above that consistent with the Eddington limiting luminosity ($\sim 10^{38}$ erg s^{-1}), then $\sim 10^8$ yr are required before the collapse takes place. The resultant explosion could observationally closely resemble that of a more conventional supernova.

We thus argue that the most likely site for the production of superheavy elements is in the surface layers of a neutron star. The most plausible means by which these layers can be returned to the interstellar medium involve the intervention, or formation, of a black hole. We should, however, mention that in certain supernova models involving a hard equation of state, it is conceivable that the central regions collapse to neutron star densities, form superheavy elements, and then bounce. This may disrupt the original star entirely, leaving no remnant at all.

Do superheavies come from neutron stars?

THE recent report of discovery of superheavy elements[1] (with nuclear charges near the predicted values for shell closure, $Z = 114$ and $Z = 126$), in surprisingly large quantities in terrestrial material, raises the question of the astrophysical sources for such nuclei. The very lightest nuclei may have been created in the first hours of the big bang, but significant amounts of elements beyond helium could not have been formed in these conditions. The heavier elements must have been formed in stars, and those as massive as uranium were probably formed by intense neutron bombardment immediately before or accompanying supernova explosions[1]. It seems unlikely, however, that superheavy nuclei could have been formed in this way, since attempts to reach the 'stability islands' by successive neutron captures must proceed by nuclei with very short lifetimes. This would almost certainly be the case for the island about $Z = 126$, if not for that at $Z = 114$. I would suggest that neutron stars might be a source for such superheavy nuclei.

Before theories of nucleosynthesis had reached their present state, Mayer and Teller considered evaporation from a fluid 'polyneutron' as a source of heavy elements[2], and came to the conclusion that nuclei with atomic masses of several hundred might be formed. With some qualification, such a polyneutron may be identified with a neutron star. We now know that the surface of a neutron star will very quickly be cooled below the crystalline melting point by neutrino emission processes[4], but it will be fluid for a short time after the collapse of a supernova core. Densities considerably higher than equilibrium values of perhaps $\rho \sim 10^{11}$ g cm^{-3} might be reached at the surface during oscillations following collapse. Evaporation of superheavies from the surface of such a newly formed neutron star would thus be virtually simultaneous with formation of heavy elements by neutron capture in the supernova explosion itself. Fission and β decay of the initial droplets of nuclear matter would be expected to yield some of the relatively stable elements about $Z = 114$, 126 and perhaps 164.

Another possibility is the disruption of a neutron star by tidal interaction with a black hole[5]. Matter can be ejected to infinity in such an encounter, and this matter might include

nuclear droplets large enough to give rise to the superheavy elements.

Spatial and temporal variations of the atmospheric sodium layer observed with a steerable laser radar

LASER radar observations of resonance scattering from atmospheric sodium during the night have, on occasions, shown evidence of short term changes in the height distribution[1–3]. It has been suggested that these changes arise from the movement of a horizontally structured sodium layer, but the measurements have all been limited to the vertical direction, and have provided no direct evidence of a horizontal variation. Evidence of horizontal structure at mesospheric heights has been provided by observations of hydroxyl emissions in the airglow, both from the ground[4] and from an aircraft[5,6]. In addition, the observed fluctuations of intensities and infrared rotational temperatures of the hydroxyl bands have been associated with the passage of atmospheric gravity waves[7,8]. We report here observations intended to examine the short term and small scale horizontal variations of the sodium layer which might also be associated with such waves.

The measurements were carried out using a laser radar system incorporating a flashlamp–pumped dye laser and a steerable mirror used for both transmission and reception. The details of the system will be described elsewhere. The steerable mirror was generally alternated between fixed angular positions with runs of ~ 500 laser pulses for each position. By this means, measurements of the height distribution of sodium at various horizontal separations were obtained.

The measurements made with the laser beam directed alternately towards the zenith and 10°E during the early morning of September 21, 1975 are shown in Fig. 1. For both directions the measurements taken during each 2–3-min interval are shown together with the standard errors; these results have been derived from the photon counts for each 1-km height interval, after allowing for the background noise

and correcting for the range dependence. The curves show, for comparison, the mean height distributions derived for each direction separately, the density scale being adjusted to give the best fit to the individual measurements near the peak. No attempt has been made to express the results in absolute sodium concentrations because of the possible variability of the atmospheric transmission coefficient and uncertainties arising from aerosol scattering in a calibration procedure based on returns from lower heights. The results shown for the two directions in Fig. 1 provide evidence of short term changes in the sodium layer which are different at locations separated by as little as 15 km at the height of the layer. Specifically, the sequence of measurements for the zenith, in comparison with the mean curve, indicates an upward movement of the layer between 0210 and 0214 or 0218 and a return to below the original height by 0227. The corresponding change in the data for the 10°E direction is seen as a downward movement between 0212 and 0216; a return to the original height, and even an upward movement, is suggested in the data for 0231. These results imply vertical movements of ~ 2 km in the sodium layer, these movements being of opposite sense at points separated by ~ 15 km. Furthermore, the suggestion of a reversal in the sense of the movement near the end of the observing period for each direction is consistent with an oscillation of period ~ 20 min. This is the first time such a small scale horizontal structure has been detected in the atmospheric sodium layer. With the data available it is not possible to distinguish between a horizontally moving structure and the passage of an atmospheric gravity wave. We note, however, that a simple interpretation of such a periodic oscillation with a horizontal wavelength of ~ 30 km in terms of a gravity wave propagating in the absence of a horizontal wind would require a vertical wavelength of ~ 7 km, whereas the vertical motions seem to be cophasal over the whole weight range of the sodium layer.

Our programme of measurements, which were carried out over eight nights during the period September 1975–January 1976, showed that, in general, the sodium layer showed little small scale spatial variation or temporal changes over periods up to ~ 1 h. This is illustrated in Fig. 2 which shows the measurements carried out on October 5, 1975 with the laser beam directed 10°E and 10°W of the zenith, corresponding to a horizontal separation of ~ 30 km at the height of the layer. The results for each direction show no evidence of any pronounced variation of the layer over the 40-min observing period. Moreover, a detailed comparison of the data on which the mean curves for the two directions are based shows that the differences are not significant. On two of the nights of observation, beam inclinations of 30° to the zenith were used, corresponding to a horizontal separation of ~ 100 km at the height of the layer. Even with this separation, significant differences

Fig. 2 Variations of the height distribution of atmospheric sodium at 10°E (*a*) and 10°W (*b*) to the vertical corresponding to a horizontal separation of ~ 30 km at a height of 85 km. The curves represent the mean of all observations shown at each angle. Data for October 5, 1975.

were observed only at heights < 82 km. In connection with this lack of variability, it should be noted that previous measurements at middle latitudes of the height variation of atmospheric temperature[9] and of very low frequency waves reflected from the D region[10] have indicated that the greatest degree of variability at mesospheric heights would be expected during winter months. It is intended to extend this type of measurement with improved system sensitivity and greater horizontal separation of the region being sounded.

We acknowledge the contributions of M. C. W. Sandford and E. Hammond to the design and construction of the laser radar system.

Atmospheric temperature calculated for ozone depletions

THE proposal that the Earth's protective ozone layer is being depleted by free chlorine produced by the photolytic decomposition of chlorofluoromethanes (CFCl₃ and CF₂Cl₂, R11 and R12) has been the subject of much discussion and controversy[1–3]. Although the effects of ozone removal on human health is a prime concern, attention has also been directed towards the possible influence on the stratospheric temperature profile[4] with associated consequences for the climate. In previous papers[4,5] it was shown that uniform depletion of stratospheric ozone leads to cooling of the stratosphere. To obtain a realistic bound on the maximum extent of stratospheric cooling, we have computed the thermal effects resulting from model D of Wofsy *et al.*[1] for ozone depletion caused by chlorofluoromethane decomposition.

In model D the authors calculated the time dependence of the atmospheric ozone profile for an assumed 10% yr⁻¹ growth rate of R11 and R12 usage (equivalent to doubling every 7 yr), assuming the 1972 emissions were 2.2×10^5 and 3.5×10^5 tonnes respectively. The decrease from the 1972 ozone profiles are shown in Fig. 1 for the years 1979, 1984, and 1996 (the ozone profiles were obtained from S. C. Wofsy, private communication).

As an input to their calculations, Wofsy *et al.*[1] used a temperature profile which was based on the 1966 standard atmosphere and assumed to remain unchanged through 1996. They report that their model gives a good representation of the ozone profile for the undisturbed atmosphere, when compared with available data[7].

To establish internal consistency in our results, we first computed a 1972 temperature profile using the Manabe–Wetherald (M–W) model[6], and the Wofsy *et al.* 1972 unperturbed ozone profile. The results were in essential agreement with Wofsy's assumed temperature profile. Next the 1979, 1984 and 1996 temperature profiles were computed assuming only that the ozone profiles changed in accordance with Wofsy's model D prediction (Fig. 1). The results are shown in Fig. 2.

As shown before[4], an appreciable temperature decrease (of the order of several degrees) was calculated in the stratosphere while a slight but uniform temperature increase was calculated throughout the troposphere. The largest change in magnitude was ~ −7.5 °C at 40 km, for a 33% ozone depletion (1996). This is similar to the results of McElroy *et al.*[7] for the stratospheric temperature effects of

Fig. 1 Percentage of ozone decrease[4], based on R11 and R12 increasing at a rate of 10% yr⁻¹ (model D).
SST fleet operations, who found a maximum temperature decrease of ~ −10 °C at 40 km. In both cases the stratospheric cooling results from a decrease in the absorption of visible and infrared radiation by ozone.

The increased uncertainty in our calculated temperature change (Fig. 2) for 44 and 48 km reflects the difficulty in treating adequately the increasingly complex spectra of the optically active atmospheric constituents at high altitudes.

Our calculated tropospheric temperature changes were 0.04 °C for 1979, 0.07 °C for 1984 and 0.16 °C for 1996, a roughly linear increase with time, at a rate of ~ 0.06 °C/10 yr. This slight surface heating is the result of more solar radiation being absorbed by the particulate layer which, in turn, heats and radiates more infrared radiation downwards to raise the surface temperature.

Similar calculations for the ozone profiles of ref. 8 give a surface temperature increase of 0.14 °C for his case I and 0.15 °C for his case II. In case I, Crutzen assumed a fixed yearly Freon release rate (equal to the world 1972 production rate) into the troposphere and determined that a steady state would be reached by the year AD 2055. Halocarbons would then be diffusing out of the troposphere into the stratosphere at the same rate at which it is being released

Fig. 2 Calculated temperature changes, based on the calculated ozone profiles of Wofsy, McElroy and Sze[5]. The 1972 temperature profile was calculated using the CO_2 and H_2O profiles described previously[4], three layers of water clouds, a surface albedo of 0.097, a background low-lying particulate layer of optical density 0.065, and 4% Rayleigh scattering. The zenith angle and length of daylight were characteristic of 30°N latitude, July. Although the M-W model does not include general circulation, it does introduce a convective contribution when the lapse rate exceeds the thermodynamic adiabatic limit.

at the surface. In these steady-state conditions he calculated that the ozone would be reduced by 7.0% of its 1972 level. For production increasing at 10% yr⁻¹ (Wofsy, model D) this change would be reached by 1987.

The Crutzen ozone profiles were also used to test the sensitivity of the temperature calculation to surface albedo. As the surface albedo was increased from 0.1 to 0.6, the stratospheric cooling increased ~ 0.4 °C while the tropospheric heating decreased ~ 0.06 °C. Thus the dependence on surface albedo seems to be of relatively minor importance in the stratosphere and of greater importance for surface temperatures.

These calculations suggest that a drop of several degrees in the stratospheric temperature might occur by the end of the century if ozone depletion proceeds according to model D of Wofsy *et al*. More recent reaction rate constants are felt to reduce these ozone depletion rates by a factor of ~ 2 (see ref. 9) and it has been found[10] that the photocross-sections for R11 and R12 are reduced at lower temperatures. In addition, it has been suggested that $ClONO_2$ may be of significance in the photochemistry of stratospheric O_3. These effects, of course, were not included in the Wofsy's calculated ozone reductions, which I have used. The importance of this temperature effect on climate (if any) has not yet been established. Since previous calculations have indicated that the thermal effect may be strongly influenced by the altitude of the maximum in the ozone profile[4], the results obtained here would be expected to vary with both latitude and season.

A possible Himalayan microcontinent

ONE of the most significant features of the Himalayan mountain chain is its crystalline core which separates the tectonic belts of the Palaeo–Mesozoic–Cainozoic rock sequences of the Himalaya in the south and those of the Trans-Himalaya in the north. This crystalline core is described as the Central Crystalline Zone[1] and the Central Barrier[2]. There are indications that the rocks of this zone are essentially a Precambrian–Proterozoic rock suite[1,2], although they were strongly remobilised during the Himalayan orogeny. No hypothesis on the evolution of this tectogene has yet explained satisfactorily the existence of the crystalline core[4,5], and taking this and the tectono-stratigraphic evidence into consideration and identifying some constraints in the existing models on the origin of the Himalaya, an alternative model, based on plate tectonics, involving microcontinents, is suggested here.

In the geosynclinal models the Central Crystalline Zone has been given distinct geotectonic status as the Central Himalayan geanticline[6], intrageanticline[7], and miogeanticline[8], but its role in such models is uncertain. There have been attempts also to fit the stratigraphic and tectonic picture of the Himalaya into an Alpine framework[9,10]. Such an attempt runs into difficulties because, although the Himalaya is a Cainozoic mountain chain, the extent and type of Meso-Cainozoic sedimentary and tectonic record do not permit a satisfactory application of the classic Alpine geosynclinal model in the Himalaya[11]. The bulk of the rocks in the Himalaya *sensu stricto* are reworked Precambrian/Proterozoic basement rocks, and Cainozoic granite–granodiorite massifs, which occur in the Axial and Inner Tectonic Belts[12], roughly defining the core of this chain (Fig. 1). A narrow zone of tectonised Palaeo–Mesozoic rocks, having a marked lateral inconsistency and strong stratigraphic breaks at places, occur to the south of these belts as allochthonous masses, thrust over the Cainozoic sediments of the Foothills. The Palaeo–Mesozoic sedimentary record is, however, fairly complete in the Tibetan zone of the

Trans-Himalaya. The most prominent and continuous dislocation zones are the Main Boundary Fault (tectonic contact of the allochthonous Pre-Tertiary rocks with the Tertiary rocks), Main Central Thrust (tectonic contact of the Axial gneisses and granites with the reconstituted Precambrian–Proterozoic rocks of the Inner Belt), Trans-Axial Thrust (tectonic contact of the Tethyan sedimentary sequence with the Axial rocks). North of the main Himalaya, the Indus–Tsangpo suture[1,18] possibly defines an ophiolite-melange zone. These dislocation zones and the character of the rock suites involved between them, seem incongruous in the regional perspective of eu–miogeosynclinal couple which is one of the fundamental tenets of the geosynclinal hypothesis.

In the plate tectonic model, the Himalaya is considered to be the classic example of a continent–continent collision system[14,15] although such a system is not yet fully understood[16]. The application of such a model[17] is faced with no fewer difficulties than those in the geosynclinal models. The plate tectonic models postulate the existence of a Tethys ocean, thousands of kilometres wide, separating India and Eurasia, before the foundering of the Gondwanaland[13,18,19], and therefore, the Himalaya is considered to have originated at the site of this consumed ocean. The crystalline axis of the Himalaya and the Palaeo–Mesozoic shallow marine and even continental sedimentary sequence to the South and North of this axis impart the main geological constraint to such models. Moreover, Tibet is mildly seismic[20] and no Tertiary to Sub-Recent volcanics are recorded in this region. The gravity data in the Himalaya clearly isolate it geophysically from the Trans-Himalayan region[21]. These facts do not fit well in a scheme involving direct collision between the Indian and Tibetan shields. Plate tectonic models are in a state of confusion, which can be realised from the fact that it is still a matter of conjecture and personal conviction as to where the junction between the Indian and Eurasian plates actually lies. The suggestions are that it lies along the Indus–Tsangpo suture[13], the Main Central Thrust[22] and even the Tien Shan[23]. These difficulties have apparently led to the suggestion[24] of a Greater India in the Gondwanaland, and to the proposal[25] that the Himalaya might represent an intracontinental mountain chain. Because of this confusion, and

considering the stratigraphic, palaeontological and palaeomagnetic data, the idea of wide oceanic separation between India and Tibet has also been criticised[15,28].

It seems that many of these inconsistencies and difficulties in the concept of evolution of the Himalaya can be overcome if this tectogene is considered to have originated through the interaction of the Indian shield and a cluster of microcontinents, instead of a direct collision between the Indian and Tibetan shields, across the Tethys. Such an interaction would account for, among other geological and geophysical attributes which characterise the Himalaya and isolate it from other segments of the Mediterranean mobile belt, the crystalline core with Cainozoic granite–granodiorite intrusives, shallow marine and platform sediments on either side of this core. The presence of a microcontinent would also imply a reduction of effective width of the Tethys which is necessary[13,28] to explain the geological picture of this region.

A strong tectonometamorphic break[27] in the Himalayan stratigraphy is indicated by extensive Permo–Carboniferous conglomerate and boulder-bed (Blaini–Rangit–Lachi). This break is linked with the Hercynian hiatus after which Gondwana sedimentation had commenced in Peninsular India. A correlation between the Precambrian–Proterozoic and Palaeozoic rocks in the Himalaya and those in the Indian Peninsula, and relict Peninsular structural grains in the Himalayan rocks[1,28] point to an inheritance of the Indian shield elements by the Himalaya. The suggestion that the Himalaya is essentially a Hercynide fold belt[29] is also relevant in this connection. It is likely that Hercynian distension caused either opening or widening of the embryonic Tethys and that during this process rifting of the northern edge of India took place, so that a cluster of microcontinents came into existence between the main continents of India and Tibet (Fig. 2). This distension was responsible for the Gondwana graben system in India and Upper Palaeozoic sedimentary-volcanic sequence in Tibet. As this process continued, the oceanic separation between the microcontinent and the Tibetan shield increased to give rise to what may be designated as the Mesozoic Tethys. In the initial stages, the Himalayan basin[30] was a rift system and an embryonic ocean, which as indicated by Upper Palaeozoic basic

evolution of the Himalaya with the
involvement of microcontinent.

volcanics in Kashmir and Eastern Himalaya, contained mantle
reaching fractures[12]. Major and trace element geochemistry
of these volcanics from a part of the Eastern Himalaya (un-
published data of the author) suggests that they are transitional
between ocean floor and 'within plate'[21] basic rock suite. Most
probably, continued rifting and distension caused appreciable
thinning of the continental crust and at a late stage, formation
of an intermediate or oceanic crust in this basin. Rift tectonics
are amply demonstrated by lateral inconsistency and temporal
heterogeneity in Upper Palaeozoic and Mesozoic stratigraphy
which ranges from marine, platform to even continental types.
Local intermingling of Gondwanic fauna with the Eurasian
types in the sediments of the Himalayan basin would suggest
that the microcontinent did not behave as a solid barrier
between the Tethys proper and the Himalayan basin. There
might have been a few isthmuses.

In late Mesozoic time the Tethys began to shrink in con-
sequence of northward drift of the Indian plate which carried
along with it the microcontinent. In early Cainozoic period the
northern edge of the microcontinent collided with the Tibetan
shield along the Indus–Tsangpo suture. The Tethyan sediments
were squeezed up and ophiolite-melange exotic blocks[1] were
thrust to the south which now occur in association with the shal-
low marine sediments deposited at the northern edge of the
microcontinent. Either a part of this microcontinent or similar
continental blocks in the Tethys might have been thrust below
Tibet to cause thickening of the continental crust in the latter.
Because the orogeny had a south-directed polarity[11], later in the
collisional sequence the northern edge of the Indian shield col-
lided with the microcontinent, probably after the suturing of the
Tibetan shield and the microcontinent. As a result, the micro-
continental basement rocks, reworked during this orogeny,
were thrust over the folded and dislocated cover sediments of
the Himalayan basin to the south. As indicated by the positive
gravity anomaly, the oceanic slab of this basin probably lies
slung beneath the mountain chain. It also seems likely that
underthrusting of this slab may be linked with the generation
of Cainozoic granite-granodiorite intrusive rocks in the
Axial zone of the Himalaya, which are difficult to explain in
plate tectonic models where direct collision between India
and Tibet is postulated. The orogenic polarity is exhibited by
the Plio–Pleistocene Siwalik molasse deposits which are con-
tained in the linear trough at the down-buckled northern edge
of the Indian shield, and which are deformed and overridden

by the allochthonous Palaeo–Mesozoic rocks, and in some
cases, even by the Precambrian–Proterozoic rocks. The bi-
phasal collision scheme suggested here is supported by palaeo-
magnetic evidence[23] provided by DSDP cores which indicates
a faster rate of northward movement of India from the Cre-
taceous to the Middle Eocene (the phase of the disappearance
of Tethys and the collision of Tibet with the microcontinent),
and a subsequent slower rate from early Oligocene (the phase
of interaction between the Indian shield and the microcontinent).
The Indus–Tsangpo suture and the Trans–Axial thrust have
been virtually inactive in recent times, but the northerly thick-
ened sediments in the Indo–Gangetic trough[24], the neotectonic
features and the seismic pattern[10,24] in the Himalaya suggest
that the main movements are localised in the microcontinental
domain, along the Main Central Thrust, and in the fold–thrust
belt to the south.

It therefore seems appropriate to conclude that the Himalaya
might indeed represent reconstituted and 'digested' upthrust
microcontinental blocks which tectonically rest over the
deformed cover rocks, deposited in the Himalayan basin.
The Tethys, if it ever existed as a very wide ocean, as normally
postulated, had little direct role in controlling the stratigraphic
composition of this tectogene.

I thank Dr B. A. Sturt for comments on the manuscript.

The sea level in the last interglacial

^{230}Th/^{234}U dating of coral terraces at 2–9 m above sea level on 'stable' oceanic islands has suggested that the sea level during the last interglacial, 120,000–140,000 yr BP (refs 1–3) was slightly higher than at present. However, accurate dating of interglacial shoreline facies on continental coasts far removed from plate boundaries has been largely neglected (the west coast of Australia[1] and Florida[4] are exceptions). Attempts have been made to date interglacial shoreline deposits from SE Australia using molluscs[5], but this has proved unreliable[6]. The recent discovery of buried corals at two localities on the E coast of Australia has provided an opportunity to determine more precise ages by ^{230}Th/^{234}U dating.

Multiple bay barriers composed of siliceous sand are a common geomorphic feature along the central and northern coasts of New South Wales. Two distinct barrier systems, the Inner Barrier and the Outer Barrier, have been recognised[7]. The Outer Barrier system is a Holocene feature, that has developed since sea level reached its present position ~ 6,000 yr ago[8]. The Inner Barrier system extends intermittently for almost 1,000 km along the coast north of Newcastle. Marine facies of this system occur at elevations of 2–8 m above present mean sea level, as determined by seams of heavy mineral and primary sedimentary structures formed on high energy, open coast beaches (tidal range ~ 2 m at spring tides). Lagoon facies are locally well developed and achieve maximum elevations of 4–6 m above mean sea level. There is no evidence of coastwise tilting of either facies in New South Wales.

The corals dated for this study come from two localities in association with the Inner Barrier, one near Newcastle (latitude 33°45′S; longitude 151°133′E), and the other near Evans Head (28°04′S; 153°27′E). In both cases the corals are in close proximity to bedrock promontories. Two coral species

from Newcastle were collected from an excavation 7 m below MSL at the base of a marine transgressive sand unit within the Inner Barrier. Corals from Evans Head were collected from an exposure behind the Inner Barrier on the south bank of the Evans River within present tidal limits. One specimen, identified as *Pocillopora damicornis*, was in its growth position, while others (*Acropora* sp., *Favites* sp.) seem to have been only slightly reworked. The corals and associated molluscan fauna suggest deposition in a shallow quiet-water lagoon, open to the sea.

The radiochemical data and ages of the corals are shown in Table 1. The corals from beneath the Inner Barrier near Newcastle give consistent ages of 143,000 and 142,000 yr BP (±12,000). The corals from behind the Inner Barrier of Evans Head gives ages ranging from 112,000–127,000 yr BP; the *in situ* coral has an age of 118,000±9,000 yr BP These dates confirm that the Inner Barrier was formed during the last interglacial. Of the five samples from Evans Head two are considered to be unreliable even though their ages agree reasonably well with the others. One coral (74630127) has a high uranium concentration and a high ^{230}Th/^{234}U activity ratio. The other coral (74630128) has a ^{234}U/^{238}U activity ratio greater than that of modern corals, and it also has a very high ^{230}Th/^{232}Th activity ratio.

The corals from Evans Head are ~ 20,000 yr younger than those from Newcastle. Evidence from New Guinea[9,10], Jamaica[11], and Timor (J. Chappell, personal communication), suggests that there were two stands of high sea level during the last interglacial at ~ 120,000 and 135,000 yr BP, with possibly a minor regression in between. The stratigraphy and morphology at the two coral sites in New South Wales indicate that the coral deposits near Newcastle could have been formed during a marine transgression before the 135,000-yr BP high sea level, while the Evans Head corals did not begin to grow until the second high sea level between 125,000 and 118,000 yr BP Although the pattern of dates from Newcastle and Evans Head are generally consistent with those established from coral terraces of tectonically uplifted areas, the precise relations between dated corals, highest sea levels reached during the last interglacial, and deposition of the Inner Barrier, are not well enough understood to establish an interglacial sea level curve for eastern Australia. The relationships between barrier and lagoon facies are, however, clear enough to point to a sea level during the final phase of the last interglacial ~ 4–6 m above present sea level.

It is difficult to determine the precise elevation of interglacial sea levels on oceanic islands. The last interglacial terrace on oceanic islands varies between 2 and 9 m above present sea level[1]. The unstable nature of many oceanic islands, and the uncertain position of dated corals with respect to sea level at the time of growth probably accounts for such differences. There is also the problem of the relationship between relative sea levels inferred from oceanic islands and those from continental coasts resulting from differences in their respective hydro-

**In situ.*

isostatic behaviour[1,11]. Nevertheless, for oceanic islands and continental coasts not located near plate margins the degree of difference may be < ±2 m. The maximum relative mean sea level for the unwarped New South Wales interglacial deposits based on elevations of lagoonal–tidal flat surfaces is 5±1 m. This compares quite well with the recent estimate of 7.6 m for the 120,000-yr-old Waimanalo shoreline on Oahu, Hawaii[6].

In New South Wales, there is no clear evidence for marine deposition older and higher than those of Inner Barrier age. The outer continental margin is subsiding at the rate of 0.01 m per 103 yr determined from seismic and bore data from eastern Australia, a figure comparable with similar continental margins elsewhere[14]. Therefore, it is likely that sea level returned approximately to the same position, or slightly lower, during each succeeding interglacial over at least the past 700,000 yr (ref. 15). In the documented spectrum of Quaternary sea level oscillations, the last interglacial appears to. have been an exceptional event in so far as it was characterised by a great ocean water volume and warm sea temperatures[15,16]. Inner Barrier elevation and faunal composition further support this conclusion that global ice volumes were smaller in the last interglacial than at present.

The authors are indebted to Drs J. Veron and J. W. Pickett for identifying corals and molluscs, and to Drs R. McLean and P. Roy for assistance in field sampling.

Stab initiation of explosions

MECHANICAL initiation of fast reactions in solids can be achieved by various methods: impact[1,2], friction[3], and shock[4]. Although it is now generally accepted that the initiation starts with the degradation of mechanical energy to heat, the precise mechanisms by which the energy conversion takes place are not understood clearly. I am concerned here with the initiation mechanism in a column of a compacted solid primary explosive when stabbed with a hard small angle metallic conical striker, which I show to be frictional. A model is presented, which, for the first time, gives a quantitative estimate of the maximum temperature rise generated during the impact.

The model is based on experimental investigations of the deformation behaviour of compacts of various reactive materials (silver azide, lead azide, lead azotetrazole) when hit with steel conical indenters. These indenters had semi-apex angle 15°, were polished to a surface roughness of 5 μm and had a flat tip of diameter 15 μm. The compact of a selected material (particle size up to 25 μm) was made in an aluminium cylindrical container, 4.3 mm in diameter, 4.8 mm high and 0.25 mm wall thickness, by placing a quantity of the material in the container and compressing with a tightly fitting cylindrical punch to a load
Fig. 1   Adhesion of particles to the indenter tip during penetration.

of 215 kg. Indentations were carried out using an Instron machine (crosshead speed 0.166 mm s⁻¹) and it was found that the load, L, and indenter penetration, x, were connected by

$$L = k_1 x^2 \tag{1}$$

where k_1 is a constant. An important observation was that during the indentation surface particles of the compact became firmly attached to the indenter tip and formed a thin coating on it (see Fig. 1).

Other studies on the deformation of compressed powders of inert materials with steel wedges (semi-apex angle 15°) revealed that the particle flow trajectory met the wedge surface at $\pi/2$, and this, combined with the observations described above (equation (1)), suggests that the deformation of the compact by small angle indenters can be described by plasticity theory[5] with a high value of the coefficient of friction between the indenter and the compact. This means that during the whole penetration period, the particles firmly attached to the indenter surface will rub against bulk particles with a relative velocity of $v(1 - \sin^2 15°)$, where v is the indenter velocity. On the other hand, the relative movement between the particles in other regions (that is, away from the indenter surface) of the compact will not occur for the whole period of the indentation. Moreover, as the thermal conductivity of the particles is much smaller than that of the indenter, the temperature generated at the metal/particle interface will be much smaller than at the particle/particle interface. Therefore, during indentation the maximum temperature rise will occur at the surface of the particles attached to the indenter.

Fig. 2   Calculated temperature rise against indenter penetration graphs when two conical indenters of different masses but having the same initial kinetic energy impact a column of compacted lead azide. *a*, Indenter mass 0.145 kg; velocity 0.5 m s⁻¹; *b*, Indenter mass 0.290 kg; velocity 0.353 m s⁻¹. Both indenters come to rest at a penetration of 1.16 mm. Note that the steady-state temperatures are reached well before the indenters come to rest.
To calculate the magnitude of the maximum temperature rise it is assumed that the particles attached to the indenter tip rub against a 'continuous plane surface' provided by the particles in the bulk. Now consider the case of one of the particles attached to the indenter. The frictional heat produced per second per unit area is

$$\frac{\mu v (1 - \sin^2 15^\circ) w_p}{A}$$

where μ is the coefficient of friction, A the area of contact, and w_p the normal force on the particle. For a compact, the normal force w_p for a particle of a given size can be calculated by assuming that the normal force on the surface of the indentation is uniform. The temperature rise can then be calculated by using the method of Blok[6] (any temperature rise from chemical reactions is neglected). If the contact area is circular of radius R, and q_1 and q_2 are the fractions of heat going into the particle and the plane surface, respectively, (that is, $q_1 + q_2 = 1$), the temperature rise ΔT at the centre of the contact area after a time t is given by

$$\Delta T = \frac{4}{\pi^{\frac{1}{2}} \rho c} \int_0^t \frac{q_1 \mu v (1 - \sin^2 15^\circ) w_p (1 - \exp(-R^2 \rho c / 4t))}{2A(4\lambda t / \rho c)^{\frac{1}{2}}} dt \quad (2)$$

where ρ is the density, λ the thermal conductivity, c the specific heat and

$$q_1 = \left[1 + \sqrt{\left(\frac{\pi}{2} \frac{v(1 - \sin^2 15^\circ) R \rho c}{4\lambda} \right)} \right]^{-1}$$

Now we can calculate the maximum temperature rise when a conical striker (semi-apex angle 15°) of mass M is dropped on to a compact for which the value of the constant k_1 (equation (1)) has already been determined by experiment. The motion of the indenter will be given by

$$M \frac{d^2 x}{dt^2} = -k_1 x^2 \quad (3)$$

This can be integrated to give the indenter velocity as a function of time. Then, by using equation (2), we can calculate the temperature rise at any time (or penetration) during the impact.

As an example, the temperature rise is calculated when a conical striker, mass 0.145 kg, strikes a compact of lead azide (compaction pressure 14.8 kg mm^{-2}) with an initial velocity of 0.5 m s^{-1}. Lead azide has been chosen since all the parameters in equation (2) are known and are:

$w_p = 2.27 \times 10^{-2}$ kg (for a particle 25 μm across)
$k_1 = 3.53$ kg mm^{-2}
$c = 4.85 \times 10^2$ J kg^{-1} K^{-1}
$\lambda = 16 \times 10^{-2}$ J m^{-1} s^{-1} K^{-1}
$\rho = 4.7 \times 10^3$ kg m^{-3}
$\mu = 0.28$ (for the case of plastically deformed contact, see ref. 7)
$R = 6.4$ μm (the value of R was obtained separately by compressing a lead azide particle against a rigid surface by a load equal to the normal force on a particle of that size during the indentation of the compact).

The results of the calculations are shown in Fig. 2. Curve a is for a 0.145-kg indenter, whereas curve b is that for a 0.290-kg indenter, but with the same initial kinetic energy as before. It will be seen from Fig. 2 that the temperature rise first increases quite rapidly with penetration, but its increase then slows down, and reaches a 'steady-state' value well before the indenter comes to rest. Note that the value of the steady-state temperature rise for the 0.145-kg indenter is 118 K, whereas it is 93 K for the 0.290-kg indenter and also that, for a given penetration, the 0.145-kg indenter gives a higher temperature. This explains the observations from stab sensitivity tests of an explosive carried out with indenters of different masses that the efficiency of

initiation of reaction is higher for the indenter of smaller mass.

The steady-state temperature for the 0.145-kg indenter is 118 K plus the initial temperature of lead azide (293 K), giving 391 K; the ignition temperature of lead azide is ~ 620 K and therefore initiation of reaction is not to be expected, as is found experimentally. The same impact conditions are, however, just sufficient to cause initiation of reaction in lead azotetrazole whose ignition temperature is 493 K. The coefficient of friction for lead azotetrazole is twice that for lead azide, but the other physical properties of the two materials are similar. The estimated steady-state temperature is ~ 530 K. Therefore we expect a higher ignition probability for lead azotetrazole than for lead azide.

Our model also predicts that reaction initiation should occur at the indenter tip after the indenter has penetrated a certain minimum distance (for a given initial velocity of the indenter). High speed photographic studies of initiation of reaction in compacts of lead azotetrazole support these predictions, and a detailed account will be published elsewhere.

I would like to thank Professor D. Tabor, Dr J. E. Field and Dr J. T. Hagan for discussion and comment. The work was supported by the Procurement Executive, Ministry of Defence.

Novel electrochemical reactor

THE past decade has seen a revival of interest in most areas of electrochemical technology because of its relevance to some of the more important problems of modern society, such as environmental pollution, scarcity of natural resources and energy conservation. Electrochemical processes are quite unique in the sense that they do not need any chemical to carry out oxidation reduction reactions, instead the energy transfer is by an inert electrode. Consequently processes are generally 'clean' and do not create undesirable waste products.

The major limitation for the widespread use of electrochemical processes has been the unsatisfactory development of electrochemical reactors, but recently[1] there has been increased activity in this area. Most electrochemical processes are limited by mass transfer rates, and attempts have been made to develop reactors with greater mass transfer capabilities, for example the fluidised bed, the packed bed and other three-dimensional particulate reactors[2,3]. The limitations of these are well documented[4,5], especially the non-uniformity of electrode potential generated by poor electronic contact between the particles.

We have developed a novel electrochemical reactor based on packed carbon fibres as the working electrode. The primary design characteristic in this reactor is the increase of mass transfer rates while simultaneously having a controllable and uniform electrode potential over the entire electrode surface. The carbon fibres, which are produced by the thermal decomposition of polyacrylonitrile, have very favourable properties as electrode materials because of their high electrical conductivity and hard vitreous surface. They also show favourable hydrogen and

oxygen overvoltage characteristics with a working range of −1.4 to +1.2 V SCE in neutral solution. This gives a wide window which is especially important in the anodic range. The most outstanding property of carbon fibres for our use is their enormous surface area. Fibres are typically 5–10 μm in diameter so that 1 g of carbon fibre has a surface area of 2.6×10^6 cm (ref. 6). This is ∼ 1,000 times larger surface per unit volume than other types of particulate reactor.

As a result of the increased surface area, the mass transfer rates in this type of reactor approach those achieved by some heterogeneous catalytic reactors; as a consequence it should have immediate impact on a wide range of electrochemical processes which were hitherto economically and technologically unfeasible. As an example we can cite an application of environmental importance, the electrowinning of trace toxic metals from effluent.

The reduction of Cu^{2+} was taken as an experimental reaction, and it was found that for a 100 p.p.m. solution at a flow rate of 3.0 ml min⁻¹ a 99.3% conversion was achieved in a single pass through the reactor with a 12-s residence time. This compares to a residence time of 1–4 h for 95% conversion in packed bed and parallel plate reactors. This performance is several orders of magnitude greater than anything achieved by other reactor designs, the major improvements in the mass transfer rates arising from (1) the large surface area of fibres, (2) the low porosity and low adsorption characteristics of the fibres and (3) the fluid flow profiles in the reactor.

Scale up studies of the reactor are currently in progress, keeping the ratio of electrode area to reactor volume constant, and reactors of 10 l h⁻¹ capacity are now functioning. The optimum bed depth of carbon fibres is 1 cm. Although the primary design consideration was for mass transfer controlled reactions, it has been found advantageous as well to carry out kinetically controlled reactions in this reactor. Various electrochemical processes are being investigated using this reactor and in all of them the major advantages are:

(1) The reactor can operate at lower current densities without corresponding decrease in yield, resulting in a sharp decrease in the cost per unit of production.

(2) It is possible to operate reactions with high yield at realistic time scales.

(3) The decrease in capital cost because they can be operated in a single pass process by having appropriate design parameters.

This should lead to substantial cost saving for all processes. Details of further work with this reactor will be reported in later publications.

Equilibrium bicontinuous structure

BICONTINUOUS partitioning of a volume is produced by inscribing a continuous, orientable surface of positive genus without self-intersection. This divides the volume into two multiply connected, interpenetrating subvolumes, each of them physically continuous (mathematically connected). Neither on a line nor in the plane is there an analogue. A bicontinuous structure is a bicontinuous partitioning in which each subvolume is filled with a distinct, not necessarily uniform composition or state of matter. In familiar examples one subvolume is solid or semi-solid, for example sandstone or sponge. An interspersion of two phases is bicontinuous only if each phase is connected across the specimen.

The idea put forward here is that bicontinuous structures may arise in fluids. The possibility of fluid analogues of porous media seems not to have been noticed before. The writer finds no mention of it in the literature on macroemulsions, periodic colloid structures, microemulsions, micellar solutions, mesomorphous phases and lyotropic crystals. Microemulsions, micellar solutions and mesomorphic phases are equilibrium states that typically consist of appreciable amounts of water, hydrocarbon and amphiphile[1,2]. Some display cubic symmetry, which is interpreted in terms of discontinuous submicroscopic globs of one composition dispersed in a continuum of another[3]. An alternative is a periodic bicontinuous structure. For thermally disrupted, non-periodic bicontinuous structures, leading candidates are optically isotropic, light-scattering microemulsion phases containing comparable amounts of water and hydrocarbon[1,4]; when one predominates, the other is often solubilised within discrete micellar structures of amphiphile. In microemulsion saturated with water and hydrocarbon, however, there is evidence that if discrete structures exist they are neither globular, tubular nor lamellar on the average and the continuous zone is dominated by neither water nor hydrocarbon[5]. The structural scale is beyond resolution by light microscopy and probably falls in the range 5–80 nm.

Intermolecular forces can conspire to elevate three energy effects to rule structure in this range. One is a sharp energy minimum when water and oil are everywhere segregated by a sheet of oriented amphiphilic molecules, the sheet constituting a partitioning surface, whether continuous or discontinuous. The second is a monotonic decrease of energy with decreasing area of the partitioning surface. The third is a sharp energy minimum with respect to the lattice parameter and symmetry of periodic structures, or mean scale length in partly randomised, isotropic structures. These three effects lead to a problem of constrained minimisation of area.

Fig. 1 Process for transforming a simple cubic array of spheres into a periodic bicontinuous structure of fused truncated octahedra with the same symmetry, lattice distance and volume fraction of one-half. The net area change is a decrease of 15%.
Table 1 Fused polyhedra compared with dispersed spheres in cubic arrays

	Simple cubic	Body centred	Face centred
Polyhedral subvolume	Truncated octahedra	Corner-notched	Truncated cuboctahedra
Complementary subvolume ('voids')	Truncated octahedra	Cubes and slabs	Truncated tetrahedra and truncated cubes
Volume fraction when areas are equal	0.40	0.53	0.57
Volume fraction when spheres are close-packed	0.52	0.68	0.74
Volume fraction when complementary subvolume becomes discontinuous	0.83	1	0.91
Area ratio when volume fraction is $\frac{1}{2}$	0.85	1.04	1.07
Range of volume fractions at which fused polyhedra have less total area	0.40–0.52	0.32–0.47	0.26–0.43
	0.48–0.60	0.53–0.68	0.57–0.74

Calculations show that, for cubic symmetries, there are intermediate ranges of the ratio of the two subvolumes, within which a bicontinuous structure is favoured over dispersion of either subvolume as separate spheres. Examples are fused polyhedra with the same cubic symmetry and lattice parameter as the arrays of spheres, each polyhedron having originally as many vertices as the coordination in the array. Areas at fixed volumes fractions are compared in Table 1; a process for making comparisons is pictured in Fig. 1. Notice that with body-centred and face-centred lattices there is a gap around volume fractions of $\frac{1}{2}$, in which dispersed spheres are again favoured.

Fused polyhedra represent upper bounds on partitioning area when symmetry, lattice parameter and volume ratio are fixed: the area can be further reduced by rounding edges and warping faces. The ultimate is a periodic minimal surface[6,7]. According to an unrefereed note[8], 17 intersection-free, infinite, periodic surfaces of cubic and other symmetries have been discovered. Portions of two are shown in Fig. 2 (refs 8, 9). With few exceptions[7] areas and volume fractions are unreported. Nor has their stability been studied. 'Almost periodic' and otherwise less regular minimal surfaces of high genus seem not to have been examined mathematically.

Minimal surfaces have no mean curvature and satisfy the Young–Laplace equation for menisci between immiscible bulk phases at the same hydrostatic pressure. Thus minimal surfaces of high genus might occur, if only transiently, as part of the interface in a macroemulsion, particularly in the phase-inversion range.

To account for variations in microemulsion properties Winsor[1] hypothesised that an amphiphile-dominated sheet, or partitioning surface, tends to become concave towards its hydrophilic or oleophilic side. In the concept of equilibrium bicontinuous structures this is equivalent to a fourth energy effect, a dependence of energy on curvature invariants (ref. 10, and M. L. Robbins, unpublished) or, in the extreme, a constant, non-zero mean curvature as a constraint. The minimisation problem becomes more difficult, and evidently has not been investigated even for periodic surfaces.

Equilibrium is governed by free energy, which encompasses entropic contributions besides energy effects. Thermal motions have to be accounted for in principle by identifying all energy states accessible to the system, in practice only those with energies close to that of the most probable state. Statistical thermodynamics indicates that thermal fluctuations can alter lattice distance and symmetry in periodic bicontinuous structures and that as temperature rises, periodicity and symmetry can be destroyed by the ever-greater shape excursions by the partitioning surface. On microemulsion scales these excursions are likely to cause connectivity fluctuations through pinching off and rewelding of narrow necks. As composition or temperature change and the energy minimum grows shallow compared to kT, this action can gradually yet completely destroy the continuity of one of the subvolumes, and then further reduce its mean coherence length until it is a dispersion of globs in the other subvolume. This may explain a striking feature of water–oil–amphiphile microemulsions: their continuous evolution into

a water-continuous solution of oil-swollen globular micelles on dilution with water, and into an oil-continuous solution of water-swollen inverted micelles on dilution with oil[1,2].

Bicontinuous structures may be present in mesomorphic, liquid-crystal-like phases regarded as dispersions of spheres, cylinders or lamellae. As with microemulsions, experiments are needed which discriminate unequivocally among the possibilities. Basic mathematical investigations of certain genus surfaces are indicated. Statistical physics can be brought to bear on what

may be a state of matter related to ordinary liquids as porous media are to homogeneous solids[11].

Why be an hermaphrodite?

Many animals and most higher plants are hermaphrodites. The basic argument of this paper is that the sex habit of a species is determined by selection acting on the number of offspring produced by individuals of different types. The argument differs radically from most earlier explanations of the evolution of hermaphroditism (reviewed by Ghiselin)[1,2], although it is formally similar to a recent explanation[3] of sequential hermaphroditism, in which individuals function first as one sex and then the other.

Our fundamental assumptions are as follows. (1) Genes in a zygote can act as switches, directing development into one or other type (male, female, hermaphrodite), or, in hermaphrodites, can alter the relative allocation of resources to male and female functions. (The theory does not apply if sexual type is determined by cytoplasmic factors, as is sometimes the case for male sterility in plants.) (2) The total production of male plus female gametes by an individual is constrained to lie within a "fitness set", which cannot be altered by genetic change. It will be shown how the form of the fitness set determines the sex habit.

Consider, for concreteness, a plant species, and let m, f, and h be the numbers of male, female and hermaphrodite individuals

respectively in a population (counted at conception). For simplicity all individuals are assumed to have the same survival rate to adulthood. A male can produce N pollen grains, a female can produce n seeds, and an hermaphrodite αN pollen grains and βn seeds. The fitness set can then be represented as a graph of α against β, as in Figs 1 and 2.

Suppose the population produces R offspring. Assuming self-incompatibility, and using "fitness" to mean the expected number of offspring produced by an individual,

fitness of a male $= R/(m + \alpha h)$,
fitness of a female $= R/(f + \beta h)$,
fitness of a hermaphrodite $= R[\alpha/(m+\alpha h) + \beta/(f + \beta h)]$.

If the situation is to be evolutionarily stable, two conditions must be satisfied: (1) the fitnesses of any types actually present in the population must be equal, and (2) the values of α and β in hermaphrodites, if present, must be an "evolutionarily stable strategy," or ESS[4]; that is, the actual phenotype, $(\alpha^*\beta^*)$, of the hermaphrodites present in the population must be as fit as or fitter than any mutant phenotype $(\alpha\beta)$ lying in the fitness set.

Case 1. $h = 0$. Population dioecious. By condition (1), $R/m = R/f$, or $m = f$. This is the familiar conclusion that the primary sex ratio is 1:1 when the costs of male and female offspring are equal[5].

A dioecious population can be invaded by an hermaphrodite mutant if $\alpha/m + \beta/f > 1/m$; that is, if $\alpha + \beta > 1$. It follows that a dioecious population is stable only if the fitness set is concave (Fig. 1a). If it is convex (Fig. 1b), then only the hermaphrodite population is stable.
Fig. 2 An ESS which is a mixture of sexual types. If the curve is convex–concave, it may be possible for a pure sex (in this case a female) to invade. The resulting mixture is stable if (i) $\alpha^* + \beta^* > 1$, (ii) $\beta^* < 0.5$, (iii) $\alpha^*\beta^*$ is the point which maximises $\alpha/(1-\beta)$. This curve illustrates gynodioecy.

Fig. 1 a, A "fitness set" for the allocation of sex function. α is the pollen produced by an hermaphrodite, as a fraction of the total produced by a male individual. β is the corresponding parameter for a female. All possible values are assumed to be to the interior of the curve. With a concave curve, the hermaphrodite population is not an ESS, but a dioecious population is. b, Optimal resource allocation for an hermaphrodite. With a convex tradeoff curve, the hermaphrodite is an ESS. The ESS resource allocation $(\alpha^*\beta^*)$ is the point on the curve which maximises the product $\alpha\beta$.

Case 2. $m = f = 0$, $h = 1$. Population hermaphroditic. If $(\alpha^*\beta^*)$ is the phenotype of typical members of the population, and $(\alpha\beta)$ of a rare mutant, then $(\alpha^*\beta^*)$ is an ESS if the fitness of $(\alpha\beta)$ is less than or equal to that of $(\alpha^*\beta^*)$ for all points on the boundary of the fitness set. For stability against small perturbations, this requires that $(\alpha/\alpha^* + \beta/\beta^*)$ be at a local maximum when $\alpha = \alpha^*$, $\beta = \beta^*$. This is equivalent to the requirement that the product $\alpha^* \cdot \beta^*$ be a maximum (Figure 1b).

This is analogous to MacArthur's[6] conclusion that selection will maximise the product of the number of males and females in a dioecious species. If the fitness set is bounded by the line $\alpha + \beta = 1$, as will be approximately true if pollen and seed production are limited by the same resources, then the ESS is for an hermaphrodite to divide its resources equally between pollen and seeds[7].

Case 3. $h \neq 0$, $f \neq 0$, $m = 0$. Population gynodioecious. The criterion $\alpha^*\beta^*$ maximal provides a local stability criterion for a hermaphrodite population. But can a population with $h = 1$ be invaded by males or females? It can be invaded by females if $R/\beta^* > 2R$, or $\beta^* < 0.5$. Provided, however, that $\alpha + \beta > 1$ for some part of the fitness set, hermaphrodites will not be completely eliminated.

Figure 2 shows a fitness set for which the ESS is gynodioecy. Let $(\alpha^*\beta^*)$ be the stable phenotype of the hermaphrodites. Then the stable sex ratio, obtained by equating the fitness of females and hermaphrodites, is given by $f = h(1 - 2\beta^*)^8$. This implies an excess of hermaphrodites, as is in fact observed in natural populations[9]. It also implies that as the frequency of females increases, the resource allocation by the hermaphrodite shifts towards male function. This shift has also been observed[10]. The fitness of a rare mutant with a different resource allocation, $(\alpha\beta)$, is given by

$$V = R[\alpha/(m + \alpha^*h) + \beta/(f + \beta^*h)]$$
$$= R[\alpha/\alpha^* + \beta/(1 - \beta^*)]/h$$

The condition for $(\alpha^*\beta^*)$ to be an ESS is that V should be at a local maximum; which is equivalent to the requirement that $\alpha/(1 - \beta)$ should be at a maximum when $\alpha = \alpha^*$, $\beta = \beta^*$. The ESS can therefore be found by drawing a tangent as in Fig. 2.

The conditions for androdioecy, $h \neq 0$, $f = 0$, $m \neq 0$, are similar. All three types can coexist only in the artificial and unlikely case, $\alpha + \beta = 1$ exactly.

The conclusions can be summarised by saying that we would expect to find monoecy or hermaphroditism in species for which the fitness set is convex, dioecy if it is concave, and androdioecy or gynodioecy if it is concave–convex.

Are there any general reasons why fitness sets should be convex? We can offer three suggestions. (1) Low mobility: in animals, Ghiselin[1,2] has noted that hermaphroditism tends to occur in species with low adult mobility. Low mobility will tend to be associated with a convex fitness set because in such species there will be little sexual dimorphism (except perhaps dwarf males) since males will not envolve special locomotory or aggressive structures for seeking out and holding females. This means that a single individual can effectively serve both functions. Furthermore, low mobility limits male reproductive success—the number of eggs that a male can competitively fertilise (or an hermaphrodite acting as a male) should rise at less than a linear rate with resource input into male function. Note that this model assigns a different role to low mobility than the classical "low density model" as developed by Ghiselin[1,2]. Even if all the eggs produced in the population are fertilised, the convex fitness set implies hermaphroditism.

(2) Low resource overlap: in plants pollen production occurs earlier in the season, for each species, than seed maturation. The two processes therefore depend, in part, on different resources, and one would therefore expect a hermaphrodite to do better than a linear combination of male and female. In animals, brooding will imply a convex set because female expenditure will occur later than male expenditure. Ghiselin[1] has pointed out that hermaphroditism in animals tends to occur in immobile species in which individuals brood the young.

(3) Cost sharing: in insect-pollinated plants, some energy must be expended by all types on producing organs of attraction which may serve both male (pollen) and female (ovule) function. If a plant's reproductive success tends more to be limited by its ability to attract pollinators than its direct input of resources into gametes, the fitness set will tend to be convex. The conclusion depends on assumptions, which merit further investigation, on how a plant allocates resources between organs of attraction and more directly reproductive structures. It does, however, suggest that dioecy should be rarer in insect-pollinated than in wind- and water-pollinated species.

We do not claim that the selective forces associated with resource allocation are the only ones relevant to the evolution of hermaphroditism. In plants, dioecy may evolve as a mechanism to prevent self-fertilisation[11]. When associated with self-fertility, hermaphroditism may be an adaptation to situations (for example, parasitic and sessile animals; annual, monocarpic and colonising plants[12]) in which opportunities for cross-fertilisation are rare[1,2]. We have also ignored possible effects on resource allocation of factors such as sperm storage (which is common in invertebrates[1,2]) and pollen or sperm competition. Models considering these factors are now being developed and will be published elsewhere. The relative importance of these various selective forces can be determined only by comparative studies of the distribution of the sex habit, which we are undertaking.

The model outlined in this paper, and its biological interpretation, was developed independently in Utah and at Sussex.

Tip formation is regulated by an inhibitory gradient in the *Dictyostelium discoideum* slug

THE cellular slime mould *Dictyostelium discoideum* (*Dd*) has proved suitable material for investigation of pattern formation. The morphogenetic field controlling *Dd* aggregation is now uniquely well characterised[1-6]. Whether its characteristics are unique or universal is not known. Here, I help to put the slime mould into a general perspective by comparing its pattern formation with that of another well studied organism. I have used grafting experiments to investigate secondary axis regulation in the *Dd* slug. The experiments parallel the use of grafts by Wolpert and collaborators to elucidate hypostome regulation in hydra[7,8]. They show that hydra and the slug use formally similar mechanisms for axis regulation. The known features of the *Dd* aggregation control system suggest that this does not account for axis regulation in the slug. (Details of the experimental procedure are given in Fig. 1 legend.)

A tipless slug (2345) was grafted with correct polarity to a range of anterior segments. This was to test the capacity of posterior cut surfaces at various levels in the slug to inhibit tip regeneration. The result (Fig. 2a) shows a posteriorly decreasing

1 2 3 4 / 2 3 4 5
Fig. 1 Like hydra, the *Dd* slug has one obvious axis of polarity (its major axis), and a terminal organiser or dominant region (the anterior tip)[9,10]*. A second tip inserted into a slug can organise a new axis. Tip excision delays development till a new tip is regenerated. If the excised tip is replaced, regeneration is usually inhibited. Axial grafts were used to investigate the inhibition process. *a*, Large slugs (1–3 mm) were taken from growth plates and laid on non-nutrient agar[6]NC4. They were measured into five sections of equal-length (1 anterior→5 posterior) and cut at one or more section boundaries, to make desired segments (for example, 1 and 2345). *b*, Grafts were made by joining the cut surfaces of a pair of slug segments as described in the text. Anterior and posterior graft segments were always from different members of a pair of slugs approximately matched for size. Most grafts were repeated 50–100 times. Chimaeric slugs resulting from grafts usually migrated for some time before making a fruiting body.

*Hydra is bipolar, with two terminal organisers (the distal hypostome and the proximal foot). The slug is probably unipolar. Here, I compare tip regulation in the slug with hypostome regulation in hydra.

gradient in capacity to inhibit a secondary axis (linear agression: first degree coefficient = 0.22). A similar result is found for hydra[7,8,11]. The data give a reasonable fit to a linear regression line (*P* > 99.5 %) but the fit is not significantly improved for higher degree polynomial plots. Two possible trivial explanations of this result were tested and eliminated (Fig. 2*b*, Table 1).

The results above suggest that *Dd* slugs contain an axial gradient in a parameter that inhibits tip formation. If this is true, we may also expect a gradient in threshold for a response to the inhibition. The low level of inhibition at region 4/5, which is demonstrably insufficient to inhibit tip formation by region 2 (high threshold), might thus inhibit tip formation by region 5 (low threshold) in the intact slug. The results of grafts to test this prediction are shown in Fig. 2*c*. They show a posteriorly decreasing gradient in threshold, exactly as in hydra[7,8,11]. The gradient is probably nonlinear (improved fit to a second degree polynomial just significant at the 5 % level).

In hydra, secondary axis inhibition is reduced if the host organiser (hypostome) is removed just before making an axial graft[7,8]. Thus, a hydra H12/1234B56F graft makes two new hypostomes (one from each 1 region) but an H12/1234/B56F graft makes no new hypostomes and retains only the original hypostome. This result, and others, which parallel my findings in *Dd* have been interpreted (by Wolpert)[8] in terms of the following concepts.

Hypostome inhibition is proposed to be caused by a fast regulating diffusion gradient of an inhibitory substance (I). I is secreted by the hypostome and destroyed elsewhere in the hydra. The I gradient interacts with a slowly regulating gradient of similar form in a cell state variable (P). P sets the threshold for a response to I. Interactions between I and P lead to hypostome formation in a predictable way. Removal of the host hypostome causes a fall in I and enhances secondary hypostome formation at local P maxima caused by grafting. It also causes a relatively faster fall in I at the anterior end of the hydra, where

I and P concentrations are initially high, with consequent formation of an anterior hypostome. The model thus provides a rule for polarity.

Tipless slug segments were compared with their intact (tipped) homologues as inhibitors of secondary axis formation. We also tested segments lacking 12 and even 123 to seek evidence for a distributed source of tip inhibitor (Table 2). We found that removal of the slug tip never reduces secondary

Axial position of test surface
Fig. 2 Results of some grafting experiments. Ordinate, inhibition of secondary axes (axes formed by the posterior slug segment); abscissa, axial level of the cut surface in the test segment. 1, Cut between segments 1 and 2; 2, cut between segments 2 and 3 and so on. The data were obtained as results of individual experiments (8–15 grafts each). The frequency of inhibition obtained in each experiment was used as a data point to calculate regression lines, means and standard deviations. Linear regression plots are shown for 2*a* and 2*b*: a second degree polynomial for 2*c*. *a*, Test (anterior) segments 1,12,123,1234 were grafted to the standard posterior segment 2345. The plot shows a (posteriorly decreasing, approximately linear) dependence of secondary axis inhibition on the level of the cut surface in the test segment. This suggests a gradient of inhibition in the slug. Numbers of grafts for this experiment were: 1:82 2:82 3:68 4:78. *b*, A test of the possibility that the observed gradient in secondary axis inhibition reflects a gradient in adhesiveness between front cells and progressively posterior cells in the slug (with a consequent gradient in frequency of isolation of the posterior segment). The posterior segments 2345, 45, 5 were grafted to a standard anterior segment (1). These grafts show no monotonic dependence of secondary axis inhibition on level of the cut surface in the test segment (linear regression: first degree coefficient = 4.57 × 10⁻³). The possibility was eliminated. Numbers of grafts for this experiment: 1:82 3:58 4:40. *c*, Test (posterior) segments 2345, 345, 45, 5 were grafted to the anterior segment 1234. The plot shows a posteriorly decreasing gradient in the capacity of the test surface to withstand inhibition by the anterior segment. This suggests a gradient in threshold for inhibition of secondary axes in the slug. Numbers of grafts for this experiment: 1:78 2:70 3:63 4:64.

axis inhibition and neither does removal of segments back to and including segment 3. Two explanations are possible within Wolpert's type of model. (1) The *Dd* I gradient shows considerable local homoeostasis, or I diffuses very little. The tip and other distant regions are thus unimportant as a short term source of local I. P shows more homoeostasis or diffuses less than I. (2) The tip is a localised source of fast diffusing I. As in hydra, organiser (tip) removal causes a general fall in I and enhances organiser formation at local P maxima. The parameters of organiser determination and differentiation (to inhibitory competence) differ, however, between hydra and the slug. Specifically, determination and differentiation are well separated in time in hydra and not in the slug. Two slug tips developing close together may thus compete (inhibit each other). In contrast, adjacent hydra hypostomes can usually develop independently.

The second hypothesis predicts that the tip of a single chimaeric slug developing from an appropriate graft (with a tipless anterior segment) may sometimes come from the posterior

Table 1 Effect of slug length on tip inhibition

To test the possibility that the observed gradient in secondary axis inhibition arises because artificially elongated slugs (with intercalary inserts) are mechanically unstable, the grafts 1234/2345, 1234/23 and 12/2345 were compared with each other. 1234/23 gave no more inhibition of secondary axes than 1234/2345 (greater length, same anterior and posterior graft surfaces). It gave significantly less inhibition than 12/2345 (same length, anterior graft surface moved forward). The length hypothesis is ruled out and a gradient of inhibition in the slug is suggested. The figures in columns 2 and 3 are results of separate experiments.

segment. According to the first hypothesis, this result would be impossible. The prediction was tested and found true (Table 3).

The present data show that tip regulation in the *Dd* slug can be described in terms identical to those used to describe hypostome regulation in hydra. Results obtained with both organisms are well explained by assuming interactions between a fast diffusing substance (I or *r*)[8,13] and a non-diffusible or slowly diffusing substance or cell-state variable (P or *a*). In this respect, both hydra and the slug resemble a third pattern-forming system (the insect segment)[14]. These similarities suggest the existence of a general class of pattern-forming system. They indicate that insights into *Dd* pattern formation will be of general interest.

For clarity, and to emphasise similarities, I have discussed the data in terms of Wolpert's model for the regulation of hypostome formation in hydra I note that the results obtained

Tipless slug segments, and segments lacking longer anterior portions (12, 123) were compared with their intact homologues as inhibitors of secondary axis formation. None of these decapitated segments seems less effective than their homologues as inhibitors of secondary axis formation. Grafts leading to close proximity between the fronts of anterior and posterior segments gave slightly increased inhibition (2/2345 gives significantly more inhibition than 12/2345). The figures in columns 2 and 3 are results of separate experiments.

in hydra and *Dd* can be explained by at least one other type of model based on two variables[13]. There is not yet any evidence to justify commitment to a particular model.

The finding that there is an axial gradient in the capacity of a slug tip to inhibit formation of a second tip must also be evaluated in terms of what is already known about the tip as an embryonic organiser.

The tip appears first in the late *Dd* aggregate[6,9]. It is then an organiser because it is a pacemaker region, where waves of chemotactant secretion are initiated. The tip thus controls the movements of the aggregating cells. The waves have polarity (that is, propagate centrifugally), but, as far as is known,

Table 3 Fate of anterior tissue in normal and decapitated chimaeras

Graft	Fractions of grafts in which			No. of grafts
	Front tissue stays at front	Mixture of front and back tissue at front	Front tissue moves back	
12/2345	1.00	0.0	0.0	50
2/2345	0.51	1.11	0.38	47

Hypothesis 2 predicts that grafts of tipless anterior segments may give rise to chimaeric slugs in which the tip comes from the posterior segment. Grafts using tipped anterior segments should never do this. To test the prediction, we made 12/2345 and 2/2345 grafts, using a (neutral red) stained anterior segment. In 12/2345 grafts, the stained tissue always remained at the front of the chimaeric slug (there is some diffusion of dye from the stained part). In 2/2345 grafts, the whole stained piece moved backwards in 38% of cases. The slug tip was then made from white (posterior) tissue. The prediction is vindicated. The frequent posterior tip formation observed in the 2/2345 grafts implies that competition between anterior and posterior developing tips is almost unbiased in this graft. This is consistent with the strongest form of hypothesis 2 (tip as sole source of inhibitor, with little inhibition by a decapitated 2 region).

convey no scalar information. Their effectiveness as signals does not diminish with distance (*r*) from the tip[3,4,15].

The ability of an aggregate tip to inhibit formation of a neighbouring tip should work by way of entrainment of the presumptive tip tissue and its prospective field by these propagating waves. This inhibitory effect should thus be independent of *r*. The finding of a distance dependent inhibitory effect in the slug suggests that the slug tip functions differently than the aggregate tip. I suspect that this difference in function relates to the genesis of a regulative scalar pattern of differentiation in the slug[16,17]. The relevance of these findings to previous models for *Dd* pattern formation is discussed elsewhere (in preparation).

I thank Frida Vork for her help with the grafting experiments, Dorothy Parsons for typing the manuscript, and Ilse Aleven and Leen Boom for the illustrations.

Diet-induced alterations in distribution of multiple forms of alcohol dehydrogenase in *Drosophila*

IT is now well accepted that enzyme polymorphisms are widespread among organisms. Electrophoretic polymorphisms in particular have been extensively studied and discussed[1]. One enzyme, alcohol dehydrogenase (ADH) has received special attention because the relative proportions of two polymorphic forms (allozymes), Adh[F] and Adh[S], in *Drosophila*, seem to vary with environmental temperature[2,3]. The situation with regard to *Drosophila* ADH, however, is complicated by the fact that even in flies homozygous for a given electrophoretic variant or allozyme, three forms of ADH activity are observed after electrophoresis[4–6]. They are distributed in such a way that (on agar gel electrophoresis) the one which migrates most cathodally (termed ADH[5] in the Adh[F] strain) has the highest activity, but is the least stable to heat. The least cathodally migrating form (ADH[1] in the Adh[F] strain) has the least activity and is the most heat stable, whereas the third form (ADH[3] in the Adh[F] strain) is intermediate with respect to both activity and heat stability (Fig. 1*a*). These forms are termed isozymes, in order to contrast them with the allozymes described above.

We have been interested in ADH and its genes because of their potential utility in investigating gene control in *Drosophila*[7–10]. We have formulated a model to explain the mechanism of formation of the isozymes[11], according to which, the three isozymes in any one homozygous strain have the same primary structure: they are dimers of identical subunits of molecular weight 2.5×10^4 (ref. 11). The different electrophoretic mobilities of the three isozymes result from the differential, non-covalent binding of a low molecular weight, negatively charged molecule. ADH[5] has none of this molecule
Fig. 1 Schematic representation of the isozymes of Adh[F]. *a*, Migration is towards the cathode. The most intense strain is represented by a solid oval, intermediate staining by the cross-hatched oval, and the open oval represents the least intensely stained zone. *b*, Model to explain the formation of the three isozymes. The circles represent the subunits of ADH, and the triangles a negatively charged, NAD–carbonyl compound addition complex bound non-covalently to the dimer. ADH[3] has one mol of this compound bound; ADH[1], two mol (ref. 11 and J. O'Donnell, M. S. and W. S. unpublished).

bound, but ADH[3] and ADH[1] have one and two mol bound per mol of enzyme (Fig. 1*b*). The low molecular weight molecule has been tentatively identified as an addition complex of nicotinamide adenine dinucleotide (NAD[+]) and a carbonyl compound (ref. 11 and J. O'Donnell, M. S. and W. S. unpublished) of uncertain structure. (In contrast to the epigenetic mode of formation of the isozymes, the allozymes are thought to display differences in electrophoretic migration because of changes in the primary structure of the ADH protein.)

This model makes some very specific predictions. One is that if the concentration of the addition complex is increased, the relative proportion of the isozymes should change. Specifically (in the Adh[F] strain), ADH[1] and ADH[3] should form at the expense of ADH[5]. We therefore fed Adh[F] flies a number of compounds that are known to form addition complexes with NAD[+] (ref. 12). A variety of other compounds, substrates of ADH, and some related compounds were also fed. An example of the results of these experiments is shown in Fig. 2. In this experiment, 3-hydroxy-2-butanone (acetoin) was fed to adult flies for 24 h in various concentrations. There is a decrease in
Fig. 2 Effect of acetoin in fly food on the isozymes of ADH. Acetoin was dissolved in water at concentrations indicated in the figure. (Controls, C, contained no added acetoin.) The solutions were added to four separate 2.6×8-cm vials containing dry Instant Drosophila Medium (Carolina Biologicals). Fifty adult (> 4 d old) Adh[F] flies were transferred to each of the vials and incubated at 25 °C for 24 h. The vials were sealed with a layer of Parafilm. After incubation the flies were collected, homogenised in 1 ml of 0.02 M sodium phosphate buffer, *p*H 7.5, and centrifuged at 12,000*g* for 15 min. The supernatant fluids (SFs) from these flies were then used for agar gel electrophoresis according to the procedure of Ursprung and Leone[4]. The gels were stained for 1 h at 29 °C for ADH activity using the staining procedure of Vigue and Sofer[12]. The positions of migration of ADH[5], ADH[3] and ADH[1] are shown at the left of the figure. (The photograph has been processed by a high contrast procedure in order to show the results more clearly.)

the apparent activity of ADH[5] and a concomitant increase in activity of ADH[3] and ADH[1] as a function of increasing concentrations of acetoin. (With an increased period of exposure, all the ADH activity can be shifted to the ADH[1] position.) In similar experiments, the following compounds were also found to lower the apparent activity of ADH[5] and raise that of ADH[3] and ADH[1]: 2,3-butanedione, 2,3-butanediol, 1,3-butanediol, 2-propanone (acetone), 2-butanone, 2-butanol and 2-propanol (all at 1% concentration). All these compounds possess a secondary alcohol or carbonyl group, which correlates well with the marked substrate preference of *Drosophila* ADH for secondary alcohols[4].
Fig. 3 Measurement of total number of ADH molecules by immunological titration of the fly supernatant fluids (SF, described in Fig. 2) shown in Fig. 2 with anti-ADH serum. Increasing amounts of fly homogenates were added to a constant volume of anti-ADH serum (prepared as described previously[10]). The abscissa indicates the volume in μl of the SF added to a constant volume (20 μl) of antiserum. After incubation for 2.0 h at 25 °C and 0.5 h at 4 °C, the mixtures were centrifuged at 12,000g for 20 min. The activity (in U per 50 μl) remaining after centrifugation is plotted as a function of μl of the original SF added. $\triangle$, SF from control (0% acetoin) flies added to 20 μl of antiserum; $\bullet$, SF from flies subjected to 1% acetoin for 24 h added to 20 μl of antiserum; $\times$, SF from flies subjected to 2% acetoin for 24 h added to 20 μl of antiserum; $\bigcirc$, SF from flies subjected to 4% acetoin for 24 h added to 20 μl of antiserum. The slopes of the four curves obtained after a linear regression analysis of the points are 0.81, 0.66, 0.50, 0.27 U per μl of the control, 1%, 2% and 4% of SFs repsectively. The x intercept, the equivalence point, is a function of the quantity of ADH-cross-reacting material. On the other hand, the slope of the line after the equivalence point represents the ADH activity per fly. Although the slopes decline threefold as a function of increasing concentrations of acetoin in the food, the equivalence points remain about the same. The equivalence points are 20, 13, 21, and 14 μl respectively.

No significant alteration in the proportions of isozymes was found after feeding with 1% butyaldehyde, *n*-butanol, pyruvic acid, glyoxal, 1,5-pentanediol, ethanol, 1-propanol or acetaldehyde. In addition, the following compounds were fed (at 1% concentration) and were found to be lethal; cyclohexanone, cyclohexanol and 2-pentanone. Many of the other compounds caused varying degrees of mortality, but enough flies remained alive for electrophoretic analysis. No simple relationship was observed between mortality and the ability to alter the ratios of the isozymes.

The changes observed after feeding acetoin and other effective compounds are termed "conversion." This term implies that either molecules originally destined to become ADH[5], form ADH[3] and ADH[1], or that ADH[5] molecules change into ADH[3] and ADH[1] molecules. In either case, the total ADH

activity would be expected to drop (since ADH[3] and ADH[1] have lower specific activities than ADH[5]) as a result of conversion, but the total number of molecules of ADH in all forms would remain the same. The data in Fig. 3 confirm our predictions and support the interpretation that conversion is taking place.

Two other predictions of the model have been confirmed. First, since strains homozygous for the three known allozymes each display three isozyme zones after electrophoresis, it is expected that each would show a similar response to being fed the effective compounds. Indeed, we found that in strains homozygous for the Adh[D] and Adh[S] variants, there was a change in the proportions of the three isozymes such that the less cathodally migrating forms seemed to increase in activity, whereas the more cathodally migrating forms lost activity after addition of acetoin to the food.

Second, since it was postulated that the isozymes originated from changes in ADH and not some other related enzyme, no bands should appear after the feeding of effective compounds in strains lacking ADH activity. In fact, no ADH activity was detectable after electrophoresis after feeding flies of the Adh[n1] strain 1% acetoin for 24 h.

Finally, we reared flies on sterile Sang's synthetic medium[14] to test the hypothesis that microbial flora were producing some compound that was causing the normal appearance of the isozymes. No differences in relative intensity of the isozymes were observed, however, when sterile cultures were compared with cultures kept in Sang's medium with added live yeast.

The experiments reported here are important for two reasons. First, since we predicted that some compounds that are capable of forming addition complexes with NAD[+] would alter the distribution of the isozymes of ADH, the data lend additional support to our model for the origin of the multiple forms of ADH. Second, these studies show that the electrophoretic migration of ADH can be changed greatly by events presumably occurring outside the *Adh* locus. It is conceivable that mutations may arise which affect the metabolism of these carbonyl compounds such that their concentration increases, resulting in changes in migration of ADH on electrophoresis. Thus, electrophoretic variants may occur in ADH with no change in the primary structure of the enzyme. For population geneticists working with this and similar enzymes, it would seem advisable, where possible, to carry out a genetic analysis of any new variants to show that the polymorphism maps close to the structural locus of the enzyme.

The three isozymes also differ significantly in stability[15], and any alteration in the ratios of activity of the three forms could cause a shift in the heat stability of total ADH extracted from flies. Since it has been reported that natural populations are heterogeneous with respect to the heat lability of some enzymes[16], it would be reasonable in the case of ADH and related enzymes to check for differences in the activity ratios of the isozymes. Here again mutations at loci outside of *Adh* which affect the amount of NAD or carbonyl compound could very well influence the stability of the enzymes without affecting its primary structure.

Heat stability variants of esterase-6 in *Drosophila melanogaster*

It has been widely recognised that electrophoretic mobility alone does not distinguish all allelic variants of enzymes that exist in natural populations[1-4]. Recent applications of various techniques, among them examination of the heat stability of allozymes, have revealed the existence of allelic variants among allozymes with identical electrophoretic mobility[5-8]. I report here the existence and frequencies of heat-stability variants of esterase-6 in populations of *Drosophila melanogaster*, as well as an electrophoretic variant whose mobility is altered by some other, probably linked, modifier locus.

Two common alleles of esterase-6 exist in natural populations as a stable polymorphism. In addition, several rare electrophoretic variants, null alleles and heat-stability alleles have been reported[9-15]. The nomenclature of Franklin[15] has been used for esterase-6 alleles. My results show that, in the populations sampled, $Est\text{-}6^{1.00}$ is a class of two alleles which can be differentiated on the basis of heat-stability, while $Est\text{-}6^{1.10}$ is a class composed of three such alleles. Finally, $Est\text{-}6^{1.08}$ has a mobility intermediate to those of $Est\text{-}6^{1.00}$ and $Est\text{-}6^{1.10}$ when homozygous but it is indistinguishable from $Est\text{-}6^{1.10}$ when heterozygous with all other lines tested (unpublished data).

Males caught in the wild were crossed individually to females heterozygous for the marked balancer chromosome TM3[16], and a series of lines homozygous for a single third chromosome were obtained through the usual series of crosses[17]. The esterase-6 locus is located at 36.8 on the third chromosome[9]. Twenty males from each line were pooled and homogenised in 0.2 ml of 0.1 M sodium phosphate buffer, pH 6.5. Aliquots of this crude homogenate were heated for 0, 5, 10, 15, and 20 min at previously determined temperatures (57.0 °C for lines carrying $Est\text{-}6^{1.10}$, 59.5 °C for lines carrying $Est\text{-}6^{1.00}$), in a constant temperature, circulating water bath with an accuracy of ±0.1 °C. The control and heated aliquots were then subjected to starch gel electrophoresis according to the methods of Richmond[18] and scored visually for staining intensity of the esterase-6 band.

Many of the extracted chromosomes carried recessive lethal genes and such lines could not be made homozygous. In these cases, if the lethal chromosome carried the $Est\text{-}6^{1.10}$ allele, it could be examined in +/TM3 flies, for TM3 carries $Est\text{-}6^{1.00}$. Lethal chromosomes carrying $Est\text{-}6^{1.00}$ could be likewise examined by outcrossing to $Est\text{-}6^{1.10}$ homozygotes, since all wild-type progeny of such crosses would be genotypically $Est\text{-}6^{1.00}/Est\text{-}6^{1.10}$. Similar crosses involving non-lethal chromosomes, which facilitated comparison of homozygotes and F_1 heterozygotes, showed the heat stability of the relevant band
to be unaffected by being heterozygous for a second electrophoretic variant.

Figure 1*A* is a zymogram showing the two heat-stability classes found among $Est\text{-}6^{1.00}$ lines, while Fig. 1*B* shows the $Est\text{-}6^{1.10}$ heat-stability classes and the allele, $Est\text{-}6^{1.08}$, mentioned above. The class designated $Est\text{-}6^{1.10\text{-}3}$ is similar to the allele $Est\text{-}6^{F_1}$ reported by Wright and MacIntyre, while $Est\text{-}6^{1.10\text{-}1}$ is probably identical to their $Est\text{-}6^{F_2}$ (ref. 14).

It is difficult to state with certainty that the observed variation is, indeed, due to variation at the esterase-6 structural locus. The following lines of evidence are, however, consistent with such an hypothesis. (1) F_1 progeny of the crosses $Est\text{-}6^{1.00\text{-}1} \times Est\text{-}6^{1.00\text{-}2}$; $Est\text{-}6^{1.08} \times Est\text{-}6^{1.10\text{-}3}$; $Est\text{-}6^{1.10\text{-}1} \times Est\text{-}6^{1.10\text{-}2}$, and $Est\text{-}6^{1.10\text{-}1} \times Est\text{-}6^{1.10\text{-}3}$, and their reciprocals show heat stabilities intermediate to those of the parental lines. (2) F_2 progeny of the crosses $Est\text{-}6^{1.00\text{-}1} \times Est\text{-}6^{1.00\text{-}2}$ and $Est\text{-}6^{1.10\text{-}1} \times Est\text{-}6^{1.10\text{-}3}$ show segregation for heat stability not significantly different from the 3:1 ratio of stable to labile bands expected if homozygotes of the more stable allele and heterozygotes are scored as stable, while homozygotes for the less stable allele are scored as labile.

The allele designated $Est\text{-}6^{1.08}$ is exceptional. Preliminary data suggest that a second locus alters the electrophoretic mobility of the $Est\text{-}6^{1.08}$ allele, such that it is indistinguishable from $Est\text{-}6^{1.10}$. This modifier locus seems to have two allelic variants, one of which is dominant and results in this alteration. But the presence of occasional double-banded phenotypes in F_2 progeny which are segregating for the modifier locus suggests that $Est\text{-}6^{1.08}$ and $Est\text{-}6^{1.10}$ lines differ at both the structural and

the modifier locus. Thus, for the purpose of examining gene frequencies at this locus, I have considered Est-$6^{1.08}$ to be an electrophoretic allele.

Table 1 gives the observed allele frequencies among extracted lines for the esterase-6 locus, according to geographic origin, when mobility alone, and mobility and heat stability are considered. With the exception of Est-$6^{1.16}$, which occurred only once, no allele is unique to a population, although Est-$6^{1.08}$ was found only in the Bloomington, Indiana area. This is in contrast to the results reported by Bernstein et al.[5] in which two neighbouring populations of *D. a. americana*, which shared three of four electrophoretic alleles, were found to share only one of nine stability alleles. No such radical differences in the genetic similarities of populations compared were observed in the system under consideration here.

Latter[19] has proposed a measure of genetic distance between populations that is suitable for the comparison of closely related populations whose hierarchical relationship is not known. He defines two quantities: δ, a measure of average genetic distance between individuals within populations, and δ_B, a measure of genetic distance between populations. They are defined as follows

$$\delta = 1 - \tfrac{1}{2}\sum_i (p_{i1}^2 + p_{i2}^2) - \tfrac{1}{2}\sum_i [p_{i1}^2(1-p_{i1})^2 + p_{i2}^2(1-p_{i2})^2] \quad (1)$$

$$\delta_B = 1 - \sum_i p_{i1}p_{i2} - \sum_i [p_{i1}(1-p_{i1})][p_{i2}(1-p_{i2})] \quad (2)$$

where p_{ij} is the frequency of the ith allele in the jth population. The net difference between populations is thus $\delta_B-\delta$.

Values for all pairwise comparisons of the populations sampled are given in Table 2, using both electrophoretic and heat stability classes. While application of the second criterion does increase δ and δ_B, the average net difference between populations is not increased significantly. Thus, the pattern of relative constancy of allele frequencies reported by O'Brien and MacIntyre[10] on the basis of electrophoretic mobility alone is not significantly altered by application of the heat stability criterion.

Genetic distance estimates are usually based on an averaging of several loci in populations[19]. However, Hedrick[20] has pointed out that if selective forces vary from locus to locus, such averaging will tend to give deceptive results. Therefore, the use of such an approach at the one locus studied here is valid as a measure of population differences at that locus.

Analysis of the reported data does not follow the predictions of Maynard Smith[3] and King[4], who propose that such variation is selectively neutral, and that the geographically uniform patterns of gene frequencies observed are a result of the limited number of charge states which the protein can assume. If such were the case, frequencies of hidden alleles should show a more random distribution than those of electrophoretic alleles. In the case of esterase-6 in *D. melanogaster*, no significant increase in randomness of gene frequencies is evident. This fact and these data are not sufficient, however, to indicate the action of selection at this locus.

I thank Rollin C. Richmond for guidance and counsel, and Ms Carolyn Wilhelm for technical assistance. I acknowledge

Method to test inhibitory antibodies in human sera to wild populations of *Plasmodium falciparum*

PROTECTIVE antibodies are involved in acquired immunity to malaria parasites[1]. Sera from monkeys immune to *Plasmodium knowlesi* contain antibodies which depress multiplication of the parasite *in vitro*[2] by, it is believed, inhibiting the invasion of red cells by merozoites[3,4]. Antibodies inhibitory to parasites of a specific antigenic variant are of a higher titre than inhibitory antibodies which cross-react with different antigenic variants[5]. We have attempted to extend these findings to natural human infections with *P. falciparum* in The Gambia, West Africa, where *P. falciparum* malaria is hyperendemic. The entire population is exposed to infection and an effective immunity is only acquired over 4–5 yr (ref. 6). Immunity to *P. falciparum* can be passively transferred with IgG from immune Gambian adults[7].

Gambian sera were screened *in vitro* for anti-*P. falciparum* activity as follows. Ring-stage parasites obtained from infected children by venepuncture were grown through schizogony in microtissue cultures[8] containing in replicate 150 μl of supplemented medium TC-199 and 100 μl of the following sera: (1) serum from the donor of the infected red cells; (2) Caucasian AB serum collected in the United Kingdom, and (3) serum from unrelated Gambians (matched for the ABO blood group of the infected cell donor). Parasite growth after reinvasion was measured by
Fig. 1 Incorporation of ³H-isoleucine by *P. falciparum* parasites grown through schizogony *in vitro* in the presence of sera from 21 different donors. Isotope (specific activity 26 Ci mmol⁻¹) was added after schizogony to give 1 µCi per culture well. Cultures were collected 43 h later. Star, autologous serum; ○, Caucasian AB serum; ●, African adult serum. Bars represent range of values.

incorporation of ³H-isoleucine and parasite multiplication was assessed by microscopic examination of smears of the cultured blood stained with Giemsa stain.

In Fig. 1, the inhibitory effects on parasite growth of sera from 19 immune African adults are compared with the effects of two control sera. Most of the sera from African adults inhibited parasite multiplication and hence the incorporation of isotope in the ensuing growth period. In a few (4/19) sera, parasite multiplication and isotope incorporation were enhanced compared with controls. More than 100 sera from Gambians aged 1–65 yr have been tested with parasites isolated from many different children. In about 71% of the sera the multiplication rate of the parasites was at least 10% less than that in serum from the donor of the parasites. But multiplication was inhibited by 20% or more in only 61% of the sera tested and by 50% or more in only 31% of the sera tested. Besides this rather low degree of inhibition, variability in the amount of inhibition was a frequent feature when the same sera were tested against parasites from different children. Table 1 summarises data from an experiment in which 11 sera from Gambian adults were tested against parasites isolated from four different infected children; the individual sera inhibited parasites from some children but not from others.

These findings raise questions about antigenic diversity in *P. falciparum* parasites, as strong inhibitory activity might depend on correct matching of parasite (antigenic) type and antiserum. In addition, the specific inhibitory antibody response might be short lived, like the precipitating antibody response to certain *P. falciparum* antigens[9]. Matching of parasite population to antiserum was not controlled and there was no knowledge of the temporal relationship between them in the experiments discussed above, nor was there in the studies of Phillips *et al.*[10] and Mitchell *et al.*[11]. The remainder of this report concerns a method we have

devised to test known homologous or heterologous combinations of parasitised cells and sera.

Heparinised blood (17 U ml⁻¹), as well as serum, was obtained from infected children. The blood was cryopreserved in a final concentration of 10% glycerol in Ringer solution at −20 °C; the serum was also frozen. Each child was treated once with chloroquine (5 mg base per kg) immediately after the infected blood was collected and a second serum sample was obtained 1–3 weeks later, after catabolism of the antimalarial. When the second serum sample was collected, 43 of the 50 donor children no longer had a patent asexual parasitaemia. It was expected that in the interval between collection of the two serum samples, each child would develop a specific immune response to the parasite population of which a representative sample had been cryopreserved. Precipitating antibodies usually appear within a week or two of treatment[12]. To compare the inhibitory activities of the first (I) and second (II) serum samples, the appropriate frozen parasites were reconstituted and grown through schizogony *in vitro* in the presence of known homologous or heterologous sera.

Table 1 Distribution of 11 adult sera according to the degree of inhibition they produced when tested with four different isolates of *P. falciparum*

Percentage inhibition of parasite multiplication	Different isolates of infected red cells			
	1	2	3	4
None	3	0	11	1
Up to 20	5	1	0	4
Up to 40	3	2	0	5
Up to 60	0	8	0	1

Studies on the metabolism[13] of chloroquine in man indicate that the dose we administered should have reached the minimum therapeutic level by day 7, the earliest time that we obtained the second serum sample from any child. To check for any antimalarial activity through residual chloroquine, we carried out cytotoxic tests with the sera in microtissue cultures using *P. knowlesi* as a model system. The results indicated that there was an overall reduction in the uptake of ³H-isoleucine by *P. knowlesi* parasites grown in serum (II) samples, but this was not significant at the 5% level. The few (5/31) serum (II) samples that had a marked inhibitory effect on *P. knowlesi* did not consistently inhibit *P. falciparum*, nor were they among the samples taken

Table 2 *Plasmodium falciparum* multiplication in serum obtained before (I) and after (II) antimalarial treatment

System	Serum	cells	(I)	(II)	
Homologous	7529	7529	100	(12)	19
	7536	7536	100	(14)	11
	7540	7540	100	(14)	45
	7544	7544	100	(14)	219
Heterologous	7519	7529	102	(14)	20
	7523	7529	52	(14)	28
	7525	7529	42	(7)	26
	7519	7536	56	(14)	2
	7529	7536	113	(12)	4
	7519	7539	136	(14)	56
	7523	7539	133	(14)	122
	7525	7539	96	(7)	67
	7529	7539	157	(12)	67
	7536	7539	135	(14)	102
	7506	7540	52	(14)	17
	7531	7540	146	(14)	108

Results are expressed as percentage of multiplication in homologous serum (I). Triplicate tissue cultures each contained 10 µl of blood + 150 µl TC-199 + 100 µl of serum. Percentage multiplication was calculated from the mean results. Italic figures indicate number of days between antimalarial treatment and collection of serum (II).

Table 3 Uptake of ^{3}H-isoleucine (c.p.m. $\times 10^{-3}$) by *P. falciparum* grown in serum obtained before (I) and after (II, III) antimalarial treatment

System	Serum	Cells	AB	I	II		III	
Homologous	7525	7525	1.31	3.21	*(7)*	0.23	*(24)*	2.09
	7531	7531	ND	3.32	*(14)*	0.05		
	7544	7544	2.25	5.98	*(14)*	12.84		
	7580	7580	1.46	2.54	*(7)*	0.28		
	7584	7584	1.76	2.19	*(7)*	0.73		
Heterologous	7569	7584	1.76	4.13	*(13)*	1.08		

Duplicate tissue cultures each contained 10 µl of blood + 150 µl of medium TC−199 + 50 µl of serum + 10 µl of ^{3}H-isoleucine (1µ Ci per well). Incorporation values are given as means. Italic figures indicate number of days between antimalarial treatment and collection of serum (II) or (III). ND, Not done; AB, Caucasian AB serum.

only 7 d after antimalarial treatment. Factors other than residual antimalarial may account for this inhibitory activity. Furthermore, a few children returned 2–3 weeks after chloroquine treatment, with patent parasitaemias and in these children there presumably was no persistent chloroquine activity.

Data on multiplication of *P. falciparum* parasites in children's sera taken before (I) and after (II) antimalarial treatment are shown in Table 2. Parasite multiplication is given as a percentage of that in homologous (I) serum, so figures greater than 100% indicate enhanced parasite growth in homologous (II) or heterologous sera.

Marked inhibition of parasite multiplication occurred in three of the four examples shown of homologous serum–cell mixtures. In the fourth example (7544) parasite multiplication was enhanced in homologous (II) serum (see below). Table 2 also shows results obtained with four isolates of infected cells that were tested against heterologous sera. Again there was marked inhibition of parasite multiplication in most of the serum (II) samples (*t* test for 12 paired (non-independent) samples gave $P<0.001$). On the other hand, in heterologous (I) samples, inhibition occurred in only 4/12 cases (some cases of cross inhibition might be expected because all the children had been exposed previously to repeated malarial infection). The inhibitory activity of serum 7536 (II) in the homologous but not in the heterologous system (7539 cells) is notable. Specific inhibition is also suggested in the heterologous tests of serum 7523 (II) with cells from 7529 (inhibition) and 7539 (no inhibition).

Measurements of ^{3}H-isoleucine incorporation gave similar results. Table 3 shows that serum 7525 (III) taken 24 d after antimalarial treatment was less inhibitory than serum (II) obtained 7 d after treatment. Serum (II), however, was not inhibitory in the *P. knowlesi* cytotoxic assay. By contrast, serum 7544 (II) was inhibitory in the *P. knowlesi* assay but enhanced both parasite multiplication (Table 2) and isotope incorporation (Table 3) in homologous tests with *P. falciparum*. No explanation for this enhanced growth can be offered at present but it may possibly be a nutritional effect.

In conclusion, our results indicate that in most cases there was significant inhibition of parasite multiplication by children's convalescent sera. Both 'cross reactive' and specific inhibition reactions were observed. The possible roles of anti-parasitic antibodies, autoantibodies to red cells, and non-antibody effects in this system require further investigation, as does the blocking effect of malarial antigen released into the serum during infection or added experimentally.

Studies of their antigens[14] and isozymes[15] suggest that wild populations of *P. falciparum* parasites frequently consist of mixed types. At present there are no reliable methods either to measure the extent of this heterogeneity or to select components from it. The protocol we present here circumvents this problem and makes possible a test of the homologous inhibitory antibody response to a pure or mixed

population of parasites. The methods that we used to cryopreserve and reconstitute parasitised erythrocytes were unrefined but further work using 10% DMSO as the cryoprotectant has improved this aspect of the test. Consequently we feel that our method offers a practical approach to the analysis of anti-parasitic antibodies in human malaria infections. Cryopreservation of *P. falciparum*[16] can be used to look for other functional antimalarial immune responses, such as cell-mediated cytotoxic responses[17], directed against specific populations of the parasite at a particular time, and also to provide laboratories outside the tropical regions with infected blood, for example for *in vitro* drug screening.

We thank Dr Elizabeth Spalding and Mr A. K. Rahman for helping to select suitable malaria cases and obtain blood specimens from them. We also thank Dr R. S. Bray and his staff at the MRC Laboratories in The Gambia for laboratory facilities. R.S.P. was supported by a US Army Contract.

Possible repair of carcinogenic damage caused by dimethylnitrosamine in rat kidney

SINCE the discovery that cells from patients with xeroderma pigmentosum, a disease associated with a high incidence of cancer, may be unable to excise ultraviolet light-induced thymine dimers from DNA[1], and the recognition of the possibility that all carcinogens react with the DNA of the organs in which tumours are induced[2], it has been thought that repair of changes produced in DNA by carcinogens

might be important in moderating the effectiveness of these compounds. Work on the carcinogenic effect of prolonged administration of various chemicals[3], however, suggests that individual carcinogenic doses are entirely cumulative in their action, and that the carcinogenic damage is permanent and not repaired[4]. If this were correct, repair of lesions produced in DNA by carcinogens would seem to have no direct relevance to carcinogenesis. Recovery from the lethal effects of radiation was established by the classic experiments of Elkind and Sutton[5] in which cultured cells were irradiated twice with different intervals between the first and second dose; if sufficient time elapsed between the first and second dose, the effects of the doses were not cumulative. We have used an analogous experimental design to study the cumulation of the effect of dimethylnitrosamine in the induction of kidney tumours in the rat. The experiment is not yet complete, but we believe we have demonstrated that a repair process exists.

A single dose of dimethylnitrosamine induces cancer in the rat kidney. When rats are fed a protein-free, high-carbohydrate diet for 7 d before receiving the dimethylnitrosamine they will tolerate a single dose which will induce cancer in every rat[6]. A few tumours are induced in other organs, mainly in the lung, but the kidney tumours predominate and the other tumours do not kill the animal before the rats are old enough for any potential kidney tumour to have become detectable.
Fig. 1 Dose–response curve for the induction of kidney tumours 80 weeks after a single administration of dimethylnitrosamine. Rats were obtained from the same source and fed the same diet as in the experiment described in the legend to Fig. 2. Results are shown as *a*, incidence of tumours against dose; *b*, as the probit of incidence against the log of the dose; *b* Was used to predict the incidence which might have been expected if other doses had been given. It can be seen that the incidence predicted from a single dose of 32 mg kg^{-1} (52%) and from 16 mg kg^{-1} (5%) were very close to those obtained in the experiment shown in Fig. 2 (55% and 6%).

The dose–response curve for the induction of kidney tumours was determined in the USA between 1972 and 1974. From this curve (Fig. 1) it can be predicted that a single dose of 16 mg per kg body weight will induce kidney tumours in 5% of the rats 80 weeks after the dose was given, rising to 10% after 2 yr. In contrast 32 mg kg^{-1} will induce a 52% incidence at 80 weeks rising to 80% after 2 yr. We have estimated the rate and extent of recovery from carcinogenic damage from the incidence of tumours produced by one dose of 16 mg kg^{-1} followed after some time by another dose. If the two doses were to be given so close together that no recovery from the carcinogenic damage could occur, the two would be completely cumulative in their effect and would be expected to give the same tumour incidence as a single dose equal to the sum of the two doses, that is, 32 mg kg^{-1} giving a 52% incidence at 80 weeks, or 80% at 2 yr. If, however, repair of the damage
Fig. 2 Incidence of kidney tumours induced 80 weeks after a single intraperitoneal injection of dimethylnitrosamine (32 mg per kg body weight) (100 rats) a single dose of 16 mg kg^{-1} (140 rats) or by two doses, the first of 16 mg per kg body weight, the second a "nominal" (see below) 16 mg kg^{-1} 1, 2, 4, 8, 16 or 32 d later. (There were 50, 50, 60, 50, 100 and 100 rats in each group.) Male CFN rates (Carworth Farms, New City, New York) each weighing about 180 g were changed to a protein-free diet for 7 d, given an injection of dimethylnitrosamine, and then maintained on the same diet for 5 d. They were then returned to a normal rat diet (MRC 41B, Christopher Hill). The second dose was adjusted, as described in the text, so that the total amount of the kidney, when two doses were given, was believed to be the same as that resulting from a single dose of 32 mg kg^{-1}. This adjustment meant that the actual dose given (in mg kg^{-1}) 1 d after the first was 12; 2 d 13; 4 d 12.5; 8 d 26; 16 d 24 and 32 d 25. Eighty weeks after the first dose, tumours had been found in 212 of the 617 rats surviving more than 4 weeks. The upper dotted line shows the incidence produced by a single dose of 32 mg dimethylnitrosamine per kg body weight. If the doses were completely cumulative, one would expect two with the effect of 16 mg kg^{-1} to give this incidence of tumours. A single dose of 16 mg kg^{-1} gave an incidence of 6%. If the doses were not cumulative and each dose of 16 mg kg^{-1} acted independently of the other, one would expect to get twice the incidence produced by a single dose of 16 mg kg^{-1} (that is 12%) marked by the lower dotted line.

caused by the carcinogen occurs in the time between the first and second dose, a less than additive effect would be expected and, in the extreme case, when the two doses were separated by a sufficient interval, the tumour incidence would be that induced by each dose separately, that is, at 80 weeks 5%, plus 5% of the animals in which cancer was not induced by the first dose.

Dimethylnitrosamine requires metabolism for its carcinogenic activity, so the possible effect of the first dose on the metabolism of the second must be considered. The second dose must give the same extent of reaction with the critical target, as happens when the single dose is increased from 16 mg kg^{-1} to 32 mg kg^{-1}. If the first dose of dimethylnitrosamine affects the metabolism of the second, the second dose required may be greater or less than 16 mg kg^{-1}. There is evidence that the extent of methylation produced in an organ by dimethylnitrosamine provides a measure of the extent of metabolism of dimethylnitrosamine in that organ, and of the extent of interaction of the ultimate carcinogen with the crucial cellular target[6]. By measuring the extent of methylation on the 7-position of guanine in the DNA of the kidneys produced by the second dose of dimethylnitrosamine, the second dose was adjusted so that, at every interval, the presumptive total extent of reaction with the

target cells was the same. The actual doses injected are given in the legend to Fig. 2.

The rats (in two batches) were given the first dose in April or May 1974. Of the 650 rats at the start of the experiment, 617 survived longer than 4 weeks. Of these, 437 are now dead, 259 of them with kidney tumours. The results (Fig. 2) seem to show that there is no repair (that is, the doses are at least cumulative) when the two doses are separated by no more than 4 d, but that apparently complete recovery takes place when the two doses are separated by 16 d or more. The reason for the considerable difference in incidence when the doses are separated by 1, 2 or 4 d is unknown. The steep dose–response curve magnifies small errors in dose to large differences in incidence, but the incidence when the doses were separated by 4 d is much greater than expected. The absolute amount of methylation of the N-7 and O^6 position of guanine, and the effect of the first dose on the excision of the O^6-methylguanine produced in the kidney DNA by the second dose, is being re-examined to try to explain it.

It is not likely that the recovery is the result of death of damaged cells and repopulation of the kidney by undamaged cells. Even 50 mg dimethylnitrosamine per kg body weight produces little necrosis in the kidney[7], and the half life of the N-7-methylguanine produced by the carcinogen in DNA is approximately the same in the kidneys of rats given 16 mg kg^{-1} as it is in the liver of rats given a dose which does not produce necrosis (ref. 8 and P. F. S. and R. Mace, unpublished). If there had been significant death and repopulation, the apparent half life of the alkylated base would have been shortened because the cells containing N-7-methylguanine would have been lost and replaced by cells which did not contain this alkylated base. The recovery therefore results not from repopulation but from repair of the critical damage which initiates the development of cancer.

The results reported here seem to be consistent with the hypothesis that the alkylation by dimethylnitrosamine and some alkylating agents of the O^6-position of guanine in DNA is the critical chemical lesion in the induction of cancer by these compounds[9] and that the animal can protect itself by excising this altered base from its DNA[10–13]. Although the rate and extent of the excision of dimethylnitrosamine-produced O^6-methylguanine from the kidney DNA of rats given exactly the diet and dose we used has not been measured, Nicoll *et al.*[12] found that after a dose of dimethylnitrosamine, which would be the equivalent of 13 mg kg^{-1} if the dietary conditions had been the same as ours, about 30% of the O^6-methylguanine was excised from the DNA between 6 h and 15 h after the dose. No further excision took place from 15 h to 48–72 h, after which excision resumed. The block of excision parallels, and might explain, the lack of recovery from the carcinogenic effect during the first 4 d (Fig. 2) but it remains to be seen whether, when the larger dose is given to rats on a protein-deficient diet, the rate and extent of excision follow more exactly the recovery from the carcinogenic effect.

Our conclusion that carcinogenic damage can be repaired differs from that of Druckrey[3], but the conclusion is not incompatible with his results, which were obtained from experiments in which carcinogen was administered repeatedly for long periods. It is not known what happens to the products of reaction between carcinogen and cell in these circumstances, but if the carcinogen acts by reacting with one of the bases in DNA so that its base-pairing properties are altered, the effect of this reaction product could be cumulative, either through accumulation of permanent base changes formed in the progeny cells during cell division, or through inhibition by the carcinogen of the excision from the DNA of the crucial reaction product. A large dose of dimethylnitrosamine inhibits the excision of O^6-methylguanine from rat liver DNA[14] and it is possible

that prolonged treatment with smaller amounts would have the same effect.

Changes in the behaviour of teratocarcinoma cells cultivated *in vitro*

MOUSE teratocarcinoma cells have been recognised as important material for studying *in vitro* the processes of determination and differentiation that take place during normal embryogenesis[1,2]. But in order for the system to be exploited maximally, it must be possible to manipulate at will the differentiation of mass cultures of pluripotent cells into endoderm, ectoderm and mesoderm derivatives. Martin and Evans showed that they could trigger the appearance of endoderm cells in undifferentiated cultures of the SIKR teratocarcinoma line by suspending aggregates of the cells in bacteriological Petri dishes to which they could not adhere[3,4]. Within about 2 d the aggregates developed into simple embryoid bodies, resembling egg cylinders of normal embryos with an outer layer of endoderm cells surrounding a core of undifferentiated cells. In some SIKR clones, but not others, the inner cells later differentiate into neuroectoderm and mesoderm and the embryoid bodies develop fluid cysts resembling the visceral yolk sac vesicles of normal early embryos cultured *in vitro*. Not all lines of pluripotent teratocarcinoma cells, however, can be induced to form embryoid bodies in such a convenient way (ref. 5 and my observations). This could be because certain teratocarcinomas are for some reason intrinsically unable to form embryoid bodies, or because the cells can lose this ability during cultivation *in vitro*. In the course of isolating a new clonal line of teratocarcinoma cells I noticed that their ability to differentiate was strongly influenced by the way in which they were maintained *in vitro*. As long as the cells were grown on layers of feeder fibroblasts they retained the ability to form embryoid bodies but this was progressively

lost as the cells were adapted to grow on gelatin-coated dishes.

The clone used for this work came from an OTT 6050 ascites tumour derived by Dr L. C. Stevens from a 6-d strain 129/Sv mouse embryo grafted to the testis of an adult[6]. A frozen stock of the ascites tumour was acquired by Dr M. J. Evans of University College, London and went through a further six passages *in vivo* before being cloned in this laboratory. Embryoid bodies in the ascites fluid were trypsinised and dispersed into 9-cm dishes containing 3×10^6 STO mouse fibroblasts that had been treated before plating out with mitomycin C (10 μg ml^{-1}) for 3.5 h (ref. 3). When colonies of undifferentiated embryonal cells had grown, the plates were trypsinised and single teratocarcinoma cells were isolated as described by Martin and Evans[3].

Cultures were maintained by plating approximately 5×10^5 cells into a 9-cm dish containing feeder fibroblasts in Dulbecco's modified Eagle's medium with 10% calf serum and 10% foetal calf serum (Flow Laboratories). The medium was changed daily and every 2–3 d the cells were detached with 0.05% trypsin and 0.6 mM EDTA in phosphate-buffered saline, pH 7.2, and subcultured. Until they were confluent, the cultures grew as homogeneous sheets of closely packed cells which spread evenly over the fibroblasts. Provided they were maintained in this way they kept their ability to differentiate into cystic embryoid bodies. The most efficient method of triggering differentiation was to suspend aggregates of the cells in bacteriological Petri dishes after a preliminary step to remove most of the feeder fibroblasts. The mixed cultures were trypsinised briefly to give clumps of 50–200 cells and these were plated out at low density on to a standard tissue culture dish in medium with 10% foetal calf serum. Overnight the fibroblasts attached tightly but the teratocarcinoma cells formed rounded aggregates which could be detached easily and transferred to bacteriological dishes. Two to three days after transfer, all aggregates resembled simple embryoid bodies: the outer endoderm cells had numerous vacuoles and microvilli, tight junctions and a well developed endoplasmic reticulum, and were separated from the inner core of undifferentiated cells by a thick basement membrane (analogous to the Reichert's membrane of normal embryos)[5]. By day 6 most of the bodies had developed a fluid-filled cyst and by 10 d about 20% of these contained small patches of haematopoietic cells.

Attempts to adapt the cells to grow in the absence of feeder fibroblasts did not succeed until (1) the dishes were coated with 1% gelatin (swine skin Type 1 300 bloom, from Sigma), (2) the cells were initially subcultured at high density and (3) the medium was supplemented with both 10% calf serum and 10% foetal calf serum. Even in these conditions, some cell death occurred during the first few subcultures, but eventually a morphologically homogeneous population of cells was obtained which grew rapidly (doubling time 20 h) in closely packed sheets and could be subcultured every 2 d at 1×10^6 cells per 9-cm dish. For the first few weeks these cells retained their ability to form cystic embryoid bodies when challenged by being put into bacteriological Petri dishes. With longer times in culture the cells would form only simple embryoid bodies. By 2 months (approximately 25 passages) only about 25% of the aggregates differentiated at all, whereas the remainder merely enlarged and became necrotic. By 4 months almost none of the clumps formed embryoid bodies after 5 d in suspension. These cultures were not entirely incapable of differentiating, however; if they were allowed to reach very high density on gelatin-coated dishes and the medium changed every day, scattered patches of endoderm cells appeared after about a week, followed by fibroblast-like cells and neurones, but this process was always accompanied by massive lysis of the undifferentiated cells. The loss of ability to differentiate rapidly seems to be irreversible

because it could not be restored by returning the deficient cells to feeder layers for several generations. The behaviour of these cells had then become very similar to that of other extensively studied OTT 6050-derived cell lines that were selected to grow in the absence of feeder fibroblasts on gelatin-coated[7] or untreated dishes[8].

These results suggest that during adaptation to growth on gelatin-coated dishes, strong selection occurs for cells which are better able to grow on a less adhesive substratum and perhaps because of this have a reduced probability of differentiating. Many of the advantages of using teratocarcinoma cells to study determination and differentiation are therefore lost if the cells are not maintained on feeder fibroblasts.

Specific binding of a somatomedin-like polypeptide in rat serum depends on growth hormone

SOMATOMEDINS are growth hormone-dependent polypeptides that have been proposed as the mediators of the peripheral actions of growth hormone on skeletal tissue[1]. Several polypeptides with somatomedin activity *in vitro*, including somatomedins A, B and C and non-suppressible insulin-like activity soluble in acid ethanol (NSILA-s)[2-4], have been isolated from human plasma. Unique among polypeptide hormones, the somatomedins circulate in human blood complexed to binding proteins of larger molecular weight[2,4-7]. We report here the specific binding of a somatomedin-like polypeptide to distinct protein fractions in rat serum and further demonstrate that the pattern and level of this binding is dependent on growth hormone. We postulate that specific binding of somatomedin modulates the peripheral effects of somatomedin activity.

Results from our laboratory[8] have suggested that somatomedin-binding proteins prolong the half life of somatomedin activity in the circulation. In those studies, the half life of somatomedin activity derived from the serum of growth hormone-treated hypophysectomised (Hx) rats and injected into recipient Hx rats was determined. The half life of somatomedin activity from Hx animals treated with growth hormone for 10 d approached the half life of somatomedin activity derived from normal rats (3–4 h) and was significantly longer than the half life (< 15 min) of somatomedin activity derived from Hx rats treated with growth hormone for only 24 h. Furthermore, the half life of somatomedin activity that had been dissociated from serum proteins of large molecular weight by boiling in acid conditions or by chromatography on Sephadex G-50 in acid conditions before injection into Hx animals was less than 30 min. If this low molecular weight somatomedin activity was recombined with the serum proteins of high molecular weight from which somatomedin activity had been dissociated, the half life of this recombined somatomedin activity was prolonged to approximately 2 h. These experiments suggested that (1) the half life of somatomedin

Fig. 1 Sephadex G-200 elution pattern of different rat sera incubated with ^{125}I-MSA. MSA was purified from the conditioned media of a line of rat liver cells in culture by a modification of previous methods[9,10]. Briefly, MSA that had been eluted from Dowex was chromatographed on Sephadex G-75 in 1 N acetic acid. MSA eluted in three regions of activity as measured by stimulation of ^{3}H-thymidine incorporation into the DNA of chick embryo fibroblasts. Fractions constituting the middle region of activity were pooled and further purified by preparative disc electrophoresis at pH 2.7 in 9 M urea. The MSA preparation used yielded a single band in two different acrylamide gel electrophoresis systems. This MSA was approximately twice as active on a weight basis as porcine insulin in stimulating ^{3}H-thymidine incorporation into chick embryo fibroblast DNA. (This is the same specific activity reported by Smith and Temin relative to the same lot of porcine insulin[14].) MSA was iodinated by a modification of the chloramine T method[11]. A sample of 6 ng of ^{125}I-MSA ($150 \, \mathrm{Ci \, g^{-1}}$) was incubated with 0.5 ml of rat serum and 0.5 ml of Ca^{2+}-Mg^{2+}-free phosphate-buffered saline (Dulbecco's PBS) for 3 h at 30 °C. The incubation mixture was then applied to a 180-ml Sephadex G-200 column (2.6×40 cm) equilibrated and eluted with Dulbecco's PBS at 4 °C. Fractions of 2.2 ml were collected. Both ^{125}I-MSA radioactivity (●) and protein content (A_{280}) are plotted against fraction number and percentage of total bed volume. The excluded volume (V_0) was marked with blue dextran, and the included volume (indicated by the arrow) was marked with dinitrophenylalanine. The main protein peaks (— — — —) from left to right correspond to macroglobulins, gammaglobulins, and albumin. *a*, Elution pattern of normal rat serum incubated with ^{125}I-MSA. Peaks of ^{125}I-MSA are denoted by Roman numerals in order of decreasing molecular size. *b*, Elution pattern of serum obtained from Hx male Sprague–Dawley rats at least 10 d after hypophysectomy (performed when they were 90–100 g body weight)[8]. *c*, Elution pattern of serum obtained from Hx rats after 10 d of twice daily intraperitoneal injections of 100 μg of bovine growth hormone (chronic GH)[8]. *d*, Elution pattern of serum obtained from Hx rats after intraperitoneal injection of 100 μg of bovine growth hormone every 8 h for 24 h (acute GH)[8].

activity in the circulation was determined by its binding to large serum proteins and (2) these binding proteins were regulated by growth hormone.

To investigate directly the binding of a somatomedin-like polypeptide to rat serum, we have used multiplication stimulating activity (MSA), a 10,000-dalton polypeptide purified from the conditioned media of a line of normal rat liver cells in culture[9,10]. MSA has physicochemical similarities to the somatomedins purified from human plasma and shares with these polypeptides the ability to interact with the same receptors in various tissues and to stimulate

growth-related processes of certain cells and tissues in culture[2,9–13]. Specifically, the MSA preparation used for the studies reported here competes for somatomedin A binding to placental membranes[12]. Conversely, somatomedin A competes for the binding of this MSA to chick embryo fibroblasts, human fibroblasts and rat liver membranes[12]. An MSA preparation of similar specific activity also stimulates sulphate incorporation into chick embryo sternal cartilage at a concentration of $25 \, \mathrm{ng \, ml^{-1}}$ (unpublished experiments of K. Gibson and E. R. Froesch) and competes for NSILA-s binding to chick embryo fibro-
Fig. 2 Competition for ^{125}I-MSA binding to rat serum by unlabelled MSA. Normal rat serum (*a*) or Hx rat serum (*b*) were incubated for 3 h at 30 °C with 6 ng of ^{125}I-MSA in the presence (○--○) or absence (●———●) of 10 μg of unlabelled MSA as in Fig. 1. The samples were applied to a column of Sephadex G-200 and analysed as in Fig. 1. Protein content (— — — —) and radioactivity of the eluted fractions are plotted.

blasts (unpublished experiments of J. Zapf and E. R. Froesch).

^{125}I-MSA was incubated with normal rat serum and chromatographed on Sephadex G-200. Radioactivity appeared in five peaks, I–V (Fig. 1a). Only the binding to peaks II and III was specific, that is, it was abolished in the presence of excess (10 μg ml^{-1}) unlabelled MSA (Fig. 2). Binding of ^{125}I-MSA to peak I was nonspecific (Fig. 2), although the possibility of some specific binding of MSA to proteins in the peak I region has not been excluded completely. Peak IV represented free ^{125}I-MSA and peak V represented free ^{125}I as determined by the elution pattern of carrier free Na[125]I.
Fig. 3 MSA binding to a mixture of equal volumes of normal and Hx rat serum. ^{125}I-MSA (6 ng) was incubated with 0.25 ml of Hx rat serum, 0.25 ml of normal rat serum and 0.5 ml of Dulbecco's PBS for 3 h at 30 °C. The incubation mixture was then chromatographed on the same column of Sephadex G-200 as in Figs 1 and 2. Fractions were analysed for [125]I (●) and protein (– – – –).

The pattern of MSA binding to normal and Hx rat serum differed strikingly. Peak II, which represented the major specific binding area for MSA in normal rat serum, was absent in Hx rat serum. In this serum, ^{125}I-MSA bound specifically only to the peak III region (Figs 1b and 2b). MSA also bound to peak III in normal rat serum but to a lesser extent than in Hx rat serum (Fig. 1a and b).

When peaks II and III that had been isolated respectively from chromatography on Sephadex G-200 of normal and Hx rat serum were rerun individually over the same column, they eluted in a position identical to their position in whole serum (data not shown). This experiment excluded the conversion of one peak to the other. Furthermore, on the basis of the chromatographic pattern of a mixture of equal volumes of normal and Hx rat serum that had been incubated with ^{125}I-MSA, Hx rat serum did not inhibit binding of peak II (Fig. 3). Thus, an inhibitory component in Hx rat serum could not account for the absence of peak II MSA in Hx serum. These results indicated that MSA binds to distinct species, presumably proteins, in normal and Hx sera.

The different profiles of MSA binding to normal and Hx rat serum suggested that the binding pattern depended on growth hormone. This was confirmed by examining sera from Hx rats treated with growth hormone for different periods (Fig. 1c and d). Peak II, absent from Hx rat serum, reappeared after only 24 h of growth hormone treatment of Hx rats (Fig. 1d). After 10 d of growth hormone treatment, there was a further increase in the binding of ^{125}I-MSA to peak II that resulted in a binding profile virtually identical to that obtained with normal rat serum (Fig. 1c). Thus, although growth hormone increases the level of peak II MSA binding in Hx rats, the mechanism by which growth hormone enhances peak II binding remains undefined.

Growth hormone could induce the synthesis or release of the peak II-binding protein or it could modify a pre-existing protein such as peak III. Together with the observations of Cohen and Nissley[8], the above experiments suggest that the peak II binding protein prolongs the half life of somatomedin activity in serum. That is, serum containing the peak II MSA-binding protein yields a longer half life of somatomedin activity when injected into Hx animals than does serum without this binding protein.

The difference between MSA binding in normal and Hx rat serum was investigated further by a competitive binding assay (Fig. 4). After incubation of ^{125}I-MSA with unfractionated rat serum, unbound ^{125}I-MSA was separated from ^{125}I-MSA bound to serum proteins by adsorption to activated charcoal[5]. The binding of MSA to serum proteins was highly specific. Unlabelled MSA inhibited ^{125}I-MSA-binding to normal rat serum. Neither MSA that had been biologically inactivated by reduction and alkylation, human growth hormone, glucagon, human placental lactogen nor insulin at high concentrations competed effectively for ^{125}I-MSA binding (data not shown).

The specific binding of ^{125}I-MSA to normal rat serum was more than twice that to Hx rat serum (Fig. 4). In addition, serum from Hx rats treated with growth hormone for 10 d
Fig. 4 Whole serum competitive binding assay. Normal (●) and Hx (○) rat sera were dialysed for 12 h at 4 °C against 250 volumes of Dulbecco's PBS and diluted with 3 volumes of the same buffer. Dialysed, diluted serum (25 μl) was incubated with 200 pg of ^{125}I-MSA in Dulbecco's PBS containing 0.2% human serum albumin in the presence or absence of unlabelled MSA at 30 °C in a total of 0.4 ml. After 3 h of incubation, 0.5 ml of Dulbecco's PBS containing activated charcoal in 2% human serum albumin was added to the reaction mixture[6]. The samples were equilibrated for 30 min at 0 °C and centrifuged at 2,500g for 10 min. The ^{125}I radioactivity in both supernatant liquid and the charcoal pellet were determined. (In a separate experiment, free[125]I-MSA quantitatively adsorbed to the activated charcoal. ^{125}I-MSA bound to serum proteins was not adsorbed.) The[125]I-MSA bound to serum proteins in the presence of unlabelled MSA (1 μg ml^{-1}) (nonspecific binding) was equal in both normal and Hx serum and has been subtracted from the total MSA before calculating the bound MSA to free MSA ratio (B/F). Nonspecific binding, equalled 24% of total binding for this experiment. B/F is plotted against increasing log concentrations of unlabelled MSA added to the reaction mixture. The binding of MSA to normal and growth hormone-treated Hx serum would underestimate specific MSA binding to these sera if endogenous somatomedins compete with [125]I- MSA for the binding protein(s).

bound 1.5 times the ^{125}I-MSA bound by serum from un-treated Hx rats (data not shown). The concentration of unlabelled MSA required to displace 50% of the specifically bound ^{125}I-MSA was approximately the same in normal, Hx and growth hormone-treated Hx serum (Fig. 4). These data suggest that normal and Hx rat serum have similar binding affinities but different binding capacities. This interpretation is supported by the predominant binding of MSA to peak II in the mixing experiment (Fig. 3). We presume that the difference in specific MSA binding by unfractionated normal and Hx serum reflects differences in the levels of peak II and peak III-specific binding proteins in these sera.

In summary, we have shown by Sephadex chromato-graphy and a competitive binding asay that normal rat serum specifically binds a somatomedin-like polypeptide; that this binding (peak II) is growth hormone dependent, and that its presence correlates with a prolonged half life of circulating somatomedin activity. The half life of somato-medin activity in Hx rat serum is short in spite of the presence of a specific somatomedin-binding protein (peak III). This could be explained by reduced binding capacity in Hx serum (Fig. 4) or by differences in the clearance or degradation of peak III or its complex with somatomedin.

Whatever the mechanism by which growth hormone alters somatomedin binding in serum, the dependence of somatomedin binding and half life on growth hormone adds an important 'fine-tuning' modulation to the control of growth by growth hormone. Indeed, the levels of a somato-medin-binding protein may determine the levels of somato-medin in the circulation. The absence of the peak II somatomedin-binding protein in Hx rats suggests that it may be difficult to produce *in vivo* growth-promoting effects with purified somatomedins due to the predicted rapid dis-appearance of these somatomedins from the circulation of the recipient Hx animal. Confirmation of this hypothesis awaits the purification of the somatomedin-binding protein and its injection into Hx animals in combination with somatomedin.

Serum can initiate DNA synthesis in cells rendered unresponsive to insulin and somatomedin

AN understanding of growth control in animal cells requires an appreciation not only of cellular events important to multiplication, but also of exogenous agents which either initiate or influence the 'decisions' of a cell to reproduce. Serum has been reported to contain factors required for cell movement[1], viability[2], ion transport[3] and control of cell density[4]. In addition, peptides from tissue or plasma have been identified (nerve growth factor (NGF)[5], somatomedin[6], non-suppressible insulin-like activity (NSILA)[7], multiplication-stimulating activity (MSA)[8], epidermal growth factor[9], fibroblast growth factor[10]) which seem to have a physiological role in the initiation of cell proliferation. Somatomedin, NSILA and MSA are probably similar, if not identical, substances and, like NGF, seem to be structurally related to insulin[11-13]. The ability of insulin to initiate DNA synthesis in various cells[14-17] may be due to cross reactivity of the hormone with receptor sites concerned with cell multiplication[12]. Recent reports suggest that serum contains additional substances that can influence the ability of a cell to respond to agents which initiate DNA synthesis[10,18,19]. While investigating the regulatory roles of insulin and serum in the initiation of DNA synthesis in quiescent chick embryo fibroblasts (CEF), we have found a distinctive difference in the initiation capacity of these agents after the inhibition of protein synthesis. We present here evidence for the existence of a regulatory component(s) in serum which recruits cells for growth from a stage in the cell cycle position (G_0?) which is re-fractory to mitogenic peptides.

As shown before[20-22], quiescent CEF initiate DNA syn-thesis 6-8 h after exposure to insulin or serum. Based on the incorporation of ^{3}H-thymidine into trichloroacetic acid (TCA)-insoluble material, the highest levels of DNA syn-thesis were initiated by insulin at a concentration of 1-5 μg ml^{-1} and approximated only 20-50% of the maximum levels stimulated by 3% serum (Fig. 1 legend). When serum-deprived CEF were treated with cycloheximide (5 μg ml^{-1}) before exposure to insulin, however, the subsequent insulin-induced DNA synthesis in washed, inhibitor-free cultures was found to be significantly reduced in comparison with previously uninhibited insulin-stimulated cultures. Figure 1 shows that the drug-induced inhibition of insulin-stimulated DNA synthesis was time dependent. Exposure to cyclohexi-mide for 6-8 h was required to reduce ^{3}H-thymidine in-corporation to 30-50% of that seen in uninhibited, hormone-stimulated cultures (Fig. 1). The percentage of insulin-treated cells with labelled nuclei was similarly decreased from 16% in uninhibited cells to 3% in inhibitor-free cells previously exposed to cycloheximide for 8 h (Fig. 2). In serum-deprived cultures, cycloheximide (5 μg ml^{-1}) inhibited incorporation of ^{3}H-amino acids into TCA-insoluble material by 70-80% as previously shown[24]. Immediately after the cells had been washed free of inhibitor, the incorporation of labelled amino acids returned to levels characteristic of serum-deprived control cultures (Fig. 1, inset). In contrast to the inhibition of insulin-stimulated DNA synthesis after exposure to cycloheximide, a similar cycloheximide treat-ment failed to reduce the serum-stimulated response (Figs 1 and 2). Similar results have been obtained with four different lots of calf serum. The fully recoverable serum-stimulated response has also been demonstrated with serum dialysed at a neutral pH (data not shown).

By measuring the DNA content of cultures, these results were further substantiated and extended to somatomedin, also an initiator of DNA synthesis in quiescent CEF[12]. In
Fig. 1 Effect of cycloheximide pretreatment on insulin or serum-stimulated incorporation of ^{3}H-thymidine into TCA-insoluble material. CEF were prepared by trypsinisation of 11-d-old embryos[23]. Wells (diameter 16 mm) containing 12-mm glass coverslips were each seeded with 9×10^5 cells in 3% calf serum minimal essential medium (MEM) (1 ml per well). After incubation for 72 h (37 °C) in a humidified 5% CO_2 atmosphere, confluent cells (5×10^4–8×10^4 cells cm^{-2}) were washed once with Hanks' balanced salt solution (BSS) and further incubated in 1 ml of serum-free MEM for 24 h. Cells were then treated with cycloheximide at a final concentration of 5 µg ml^{-1} by the addition of small 10-µl samples from a concentrated stock of the drug. After a maximum cycloheximide treatment period of 8 h, all cells were washed twice with BSS, and then MEM with insulin (5 µg ml^{-1}) or 3% calf serum was added to wells in 1-ml volumes. After 6 h, 0.4 µCi of ^{3}H-thymidine (^{3}H-methyl, specific activity 64 Ci mmol^{-1}, Nuclear Dynamics) in MEM was added to each well. Twenty-four hours after the addition of hormone or serum, cells were washed once with cold saline (0.85%) and TCA-soluble material was extracted with cold 5% TCA (1 ml per well). After 10 min, the TCA was discarded and fresh 5% TCA added for a further 5 min. Coverslips were dipped in 95% ethanol and dried in counting vials at 50 °C. The TCA-insoluble radioactivity (c.p.m. per coverslip) was determined after the addition of Omnifluor–toluene scintillation fluid ($\triangle$, $\blacktriangle$; $\square$, $\blacksquare$). In one experiment, ($\bigcirc$, $\bullet$), after the second TCA wash coverslips were placed in small glass vials and the cells were digested with Protosol (New England Nuclear) for 2 h at 50 °C before addition of scintillation fluid. Percentage response is reported as the c.p.m. stimulated by insulin ($\triangle$, $\square$, $\bigcirc$) or serum ($\blacktriangle$, $\blacksquare$, $\bullet$) in three experiments after cycloheximide treatment for 1–8 h over uninhibited insulin-stimulated c.p.m. ($\triangle$, 25,820 c.p.m.$\pm$61; $\square$, 13,360 c.p.m.$\pm$960; $\bigcirc$, 39,095 c.p.m.$\pm$4174) or serum-stimulated c.p.m. ($\blacktriangle$, 54,414 c.p.m.$\pm$1537; $\blacksquare$, 50,160 c.p.m.$\pm$2606; $\bullet$, 84,662 c.p.m.$\pm$602), respectively. ^{3}H-thymidine incorporation in control cultures (MEM stimulated) for the three experiments averaged 2,545 c.p.m. The range and mean of duplicate determinations are shown. Inset, ^{3}H-amino acid incorporation into TCA-insoluble material in inhibited and uninhibited cultures. After treatment with (b, c) or without (a, d) cycloheximide for 6 h, cultures a and b were pulse labelled for 30 min at 37 °C with 2.5 µCi of ^{3}H-amino acids (Schwartz Mann, protein hydrolysate, 1 mCi ml^{-1}). c and d were washed twice with BSS and immediately pulsed with ^{3}H-labelled amino acids in fresh serum-free MEM for 30 min. Coverslips were then washed four times with cold saline and processed and counted as described above. The variation from the mean of duplicate samples was less than 10% in all cases. Amino acid incorporation was inhibited 71% in the presence of cycloheximide.

uninhibited cultures the DNA content 24 h after exposure to insulin, somatomedin (0.2 U ml^{-1}) or serum increased 18%, 20% and 50%, respectively (Fig. 3). In cells previously inhibited with cycloheximide (+CH) for 8 h, the increases in DNA initiated by insulin and somatomedin were either not observed or considerably reduced, again in contrast to the serum-initiated increases in DNA (Fig. 3). These data argue against the possibility that cycloheximide dissociates ^{3}H-thymidine transport and DNA synthesis, as shown with cytochalasin B treatment of 3T3 cells[26].

To explain the failure of the drug to diminish serum-stimulated DNA synthesis, it could be argued that the hormone-responsive cells inhibited by cycloheximide are

not part of the larger population of cells that responds to serum. Incorporation of TCA-insoluble ^{3}H-thymidine and autoradiography show however, that non-additive levels of DNA synthesis are obtained in cultures exposed to either of the hormones plus the maximum stimulatory concentration of serum (data not shown). This suggests that each of the hormones stimulates DNA synthesis in cell populations that also initiate DNA synthesis in response to serum. Similar findings have been reported before[7].
Fig. 2 Effect of cycloheximide pretreatment on insulin or serum-stimulated labelled nuclei. CEF were prepared as in Fig. 1. Wells (35 mm diameter) containing 22×22-mm glass coverslips were each seeded with 3×10^6 cells in 3% calf serum MEM (3 ml per well). After incubation for 72 h (37 °C) in a humidified 5% CO_2 atmosphere, confluent cells were washed once with BSS and further incubated in 2.5 ml of serum-free MEM. After 24 h in serum-free MEM, cells were treated with cycloheximide at a final concentration of 5 µg ml^{-1} by addition of 25-µl samples from a concentrated stock of the drug. After a maximum cycloheximide treatment period of 8 h, cells were washed twice with BSS, and then MEM with 5 µg ml^{-1} insulin or 3% calf serum was added to wells in 2.5-ml volumes. After 6 h 1 µCi of ^{3}H-thymidine in MEM was added to each well. Twenty-four hours after the addition of hormone or serum, cells were washed once with saline and processed for autoradiography as before[20]. Percentage response is reported as percentage of insulin- ($\blacktriangle$) or serum- ($\blacksquare$) stimulated cells with labelled nuclei after cycloheximide treatment for 3, 6 or 8 h over the percentage of uninhibited insulin-stimulated cells with labelled nuclei (16%$\pm$3) or serum-stimulated cells with labelled nuclei (58%$\pm$6), respectively. The percentage of cells with labelled nuclei after addition of MEM alone was 3%. The range and mean of duplicate determinations are shown.

The kinetics of the fully recoverable serum-stimulated DNA synthesis in CEF after cycloheximide treatment was monitored by pulse labelling cells with ^{3}H-thymidine at various times after addition of serum. Figure 4 shows that compared with uninhibited control cultures, both the onset and peak of serum-stimulated DNA synthesis were delayed by 3–5 h in cycloheximide-treated cells. In our hands, the timing of DNA synthesis in uninhibited insulin-stimulated CEF is similar to that of uninhibited serum-stimulated cells[20,27].

The delayed onset of DNA synthesis in inhibited cells after exposure to serum could account for the inability of the hormones to stimulate DNA synthesis, for during the additional time needed by cells to regain the capacity to synthesise DNA, the hormones could have been degraded. This seems unlikely, however, because media containing insulin 5 µg ml^{-1} remained fully active in stimulating DNA synthesis for at least 16 h after incubation with inhibited or uninhibited cultures. This latter observation (data not shown) was made by measuring ^{3}H-thymidine incorporation into TCA-insoluble material stimulated in fresh cell monolayers exposed to the 'used' insulin-containing media.

Thus, the ability of inhibited cells to synthesise DNA after
Fig. 3 Effect of cycloheximide pretreatment on the DNA content of CEF after the addition of insulin (INS), somatomedin (SM) or calf serum (CS). CEF were prepared as for Fig. 1. Plastic flasks (72 cm^2) were each seeded with 2.2×10^7 cells in 3% calf serum MEM (15 ml per flask). After incubation for 72 h (37 °C) in a humidified 5% CO_2 atmosphere, confluent cells were washed once with BSS and further incubated in 15 ml of serum-free MEM. After 24 h in serum-free MEM, cultures were treated with cycloheximide (5 µg ml^{-1}) and after 8 h were washed twice with 15 ml of BSS. Cells were exposed to MEM, INS (5 µg ml^{-1}) S, SM (0.2 µg ml^{-1}) or 3% CS. Twenty-four hours later the cells were washed once with saline, trypsinised (0.5% trypsin), pelleted by centrifugation and counted. The DNA content per flask (3×10^6–5×10^6 cells) was determined after treatment of cells with 1 N perchloric acid at 70 °C for 20 min, using the method of Burton[25]. The percentage increase in DNA content was determined using the A_{600} values obtained for MEM-stimulated cells as baseline (0% increase). For each bar, the variation and mean of two experiments is given. In each experiment, all points were determined in duplicate and averaged.

exposure to serum seems to require additional time-dependent cellular changes not required of uninhibited cells. In view of the inability of insulin or somatomedin to induce DNA synthesis in cycloheximide-treated cells, these further changes seem to be initiated by a serum component(s) distinct from those which signal DNA synthesis directly. In this regard, serum seems to be performing a more complex function than simply supplying inhibited cells with an exogenous nutrient needed for DNA synthesis. If this were the case, the timing of DNA synthesis might be expected to be unaffected by cycloheximide treatment[28].
To summarise and further clarify our ideas, we suggest that the inhibition of protein synthesis results in the loss of some cellular protein(s) required directly or indirectly for the induction of DNA synthesis by insulin and somatomedin, and that these agents cannot reinitiate the synthesis of this protein. An additional regulatory component(s) in serum is proposed that can signal the synthesis of this missing cellular protein(s), thus permitting the subsequent induction of DNA synthesis by factors in serum functionally analogous to insulin and somatomedin. In terms of the eukaryotic cell cycle, this additional serum component(s) could have a role in the recruitment of cells from G_0 into G_1.

We thank J. J. Van Wyk for helpful suggestions and for insulin-free somatomedin (specific activity 8.7 U per mg protein). This research was aided by a grant from the American Cancer Society to the University of North Carolina. I.B.B. is the recipient of a USPHS Career Development Award from the NIAID.

Fig. 4 Effect of cycloheximide pretreatment on the timing of DNA synthesis in CEF after the addition of serum. CEF were prepared as for Fig. 1. Glass bottles (11 cm^2) were each seeded with 4.5×10^6 cells in 3% calf serum MEM (3 ml per bottle). After incubation for 72 h in a humidified 5% CO_2 atmosphere, confluent cells were washed once with BSS and further incubated in 3 ml of serum-free MEM. After 24 h in serum-free MEM, cultures were treated with or without cycloheximide (5 µg ml^{-1}) and after 8 h were washed twice with 3 ml of BSS. Cells were treated with MEM containing 3% calf serum and pulse labelled with ^{3}H-thymidine (5 µCi per bottle) for 1-h intervals at the times indicated. Pulse-labelled cells, washed once with cold saline (3ml) were scraped into 1 ml of saline to which 7.5% TCA was added. TCA-insoluble material was collected by centrifugation, washed once with 5% TCA, and dissolved in 0.1 M NaOH (0.75 ml). Samples of 0.25 ml were added to 5 ml of scintillation fluid (Triton X-Omnifluor–toluene) and counted. The range and mean of duplicate determinations are shown. ○, Uninhibited cultures; ●, cycloheximide-pretreated cultures. Inset, DNA synthesis in control cultures for 24 h after the addition of hormone or serum. After treatment with (c, d) or without (a, b, e) cycloheximide for 8 h, cells were washed and exposed to a, MEM; b, c, insulin; d, e, serum as described above. ^{3}H-thymidine (0.4 µCi per bottle) was added 6 h after the addition of hormone or serum. Cells were collected 18 h later and the TCA-insoluble material was prepared and counted as described above. Insulin-stimulated DNA synthesis was inhibited 69% by cycloheximide pretreatment.

Magnesium required for serum-stimulation of growth in cultures of chick embryo fibroblasts

THE addition to culture medium of phosphorylated compounds which preferentially bind Mg^{2+} substantially reduces the rate of DNA synthesis and metabolism of chick embryo fibroblasts (CEF)[1]. This has suggested that Mg^{2+} might be an intracellular regulator for coordinate control of the rate of cell growth and metabolism in animal cells[1]. We report here that the omission of Mg^{2+} from the culture medium can have considerable effects on cell growth and macromolecular synthesis by CEF if the Mg^{2+} is withdrawn at the time cells are being stimulated to grow by means of an increase in the concentration of serum in the medium. These observations are discussed in terms of a model in which the intracellular concentration of free Mg^{2+} coordinately regulates the rate of metabolism and cell growth through its role as an essential cofactor for transphosphorylation reactions.

Primary cultures of CEF were prepared as before[2]. Secondary cultures were plated 3–5 d before use at 10^6 cells per 60-mm Falcon culture dish in medium 199, containing 2% tryptose phosphate broth (TPB) and 1% chicken serum. During experimental manipulation, medium 199 containing 2% TPB was again used at the indicated Mg^{2+} concentration, but with dialysed serum present. Experimental techniques for isotopic labelling, scintillation counting and autoradiography have been described before[3,4]. Concentrations of Mg^{2+} in the culture medium were determined with a Perkin–Elmer atomic absorption spectrophotometer.
Fig. 1 ^{3}H-thymidine incorporation by CEF as function of the concentration of Mg^{2+} and calf serum. Four-day-old cultures were changed to fresh medium at the indicated concentrations of Mg^{2+} and calf serum; 20 h later the rate of DNA synthesis was measured by ^{3}H-thymidine (0.6 µCi ml^{-1} medium) incorporation into acid insoluble material for 60 min (calf serum: $\triangle$, 8%; $\bigcirc$, 4%; $\bigtriangledown$, 1%; $\square$, 0.0%).

Stimulation of cell growth by serum causes an increase in the rate of ^{3}H-thymidine incorporation by CEF that is proportional to the increase of the number of cells in the S phase of the cell cycle[5]. But as Fig. 1 shows, reducing the Mg^{2+} concentration of the medium from the standard 0.8 mM concentration to 0.04 mM prevents the increase of ^{3}H-thymidine incorporation. Below 0.1 mM Mg^{2+} the rate of ^{3}H-thymidine incorporation was directly proportional to the Mg^{2+} concentration of the medium at any concentration of calf serum (or chicken serum) from 1% to 8%.

There have been reports that the addition of Mg^{2+} to culture medium is not essential for the growth of mouse L cells[6] and HeLa cells[7]. We suppose that either of those cell lines have a slightly lower Mg^{2+} requirement for growth or, in the case of the report on mouse L cells[6], the medium
Fig. 2 Comparison of total ^{3}H-thymidine incorporation and autoradiography as measures of the rate of DNA synthesis. Four-day-old cultures were changed to medium containing 0.04 mM Mg^{2+} and the indicated concentrations of dialysed calf serum. After 20 h, half of the cultures were stimulated to grow by increasing the Mg^{2+} concentration of the media to 0.84 mM. Twenty hours later ^{3}H-thymidine (0.6 µCi ml^{-1}) was added to the medium for 60 min. *a*, Half of the cultures were used to determine total ^{3}H-thymidine incorporation into acid insoluble material; *b*, parallel cultures prepared for autoradiography as described before[4]. Solid columns, 0.04 mM Mg^{2+}; hatched columns, 0.84 mM Mg^{2+}.

used might have contained more Mg^{2+} as a contaminant than was present in ours. As both of these cell lines have malignant characteristics, a reduced requirement for Mg^{2+} could also be characteristic of malignant transformation.

Figure 2 shows that Mg^{2+} deprivation of cells reduced ^{3}H-thymidine incorporation mainly by decreasing the rate
Fig. 3 Reversibility of inhibition of cell growth by Mg^{2+} deprivation. At zero time 5×10^5 CEF in medium 199 ($-Mg^{2+}$) containing 2% TPB, 5% dialysed calf serum and the indicated concentrations of Mg^{2+} were added to 60-mm culture plates. In these conditions, approximately 80% of the cells attach to the plates by 3 h. At 20 h half of all of the cultures were changed to medium containing the standard 0.84 mM Mg^{2+}. Then at 20, 44 and 68 h the number of cells on each plate was determined, after trypsin treatment, with a Coulter counter. Original medium: $\blacktriangledown$, 0.04 mM Mg^{2+}; $\bullet$, 0.06 mM Mg^{2+}; $\blacktriangle$, 0.11 mM Mg^{2+}; $\blacksquare$, 0.84 mM Mg^{2+}. The open symbols with dashed lines indicate the corresponding cultures changed at 20 h to medium containing 0.84 mM Mg^{2+}.

of entry of cells into the S phase of the cell cycle, not just by slowing the rate of DNA synthesis in individual cells. When Mg^{2+} was added back to the culture medium of cells that had been deprived of Mg^{2+} for 24 h, there was stimulation of both ^{3}H-thymidine incorporation and percentage ^{3}H-thymidine-labelled nuclei : this was directly related to the serum concentration in which the cells had been maintained during this period. In the case of Mg^{2+}-deprived cells maintained in medium containing 5% calf serum there was a 17-fold increase in the rate of ^{3}H-thymidine incorporation 20 h after addition of Mg^{2+} to the culture medium. Autoradiograms of parallel cultures revealed a 10-fold increase in the number of ^{3}H-thymidine-labelled nuclei at this time. If ^{3}H-thymidine incorporation accurately reflected the rate of DNA synthesis, then after the addition of Mg^{2+} individual cells made DNA only 1.7 times faster, but 10 times more cells were in S phase. Likewise with Mg^{2+}-deprived cultures maintained in 1% calf serum there was a fivefold increase in ^{3}H-thymidine incorporation and a threefold increase in the percentage of labelled nuclei 20 h after addition of Mg^{2+}.

Figure 3 shows the inhibition of cell multiplication by Mg^{2+} deprivation, and its reversal when Mg^{2+} was restored. At zero time 5×10^5 CEF in medium containing the indicated concentrations of Mg^{2+} were plated on 60-mm culture dishes. About 80% of the cells became attached at all Mg^{2+} concentrations. At 20 h half of all the cultures were moved to medium containing 0.84 mM Mg^{2+}. Then at 20, 44 and 68 h the cells on each plate were counted, after trypsin treatment, with a Coulter counter. By 20 h after plating-out of cultures, the cells growing in medium containing 0.84 mM Mg^{2+} had doubled in number and continued

Fig. 4 Effect of Mg^{2+} deprivation on ^{3}H-proline, ^{3}H-uridine and ^{3}H-thymidine incorporation. Five-day-old cultures were changed to medium containing 5% dialysed calf serum and either 0.84 mM Mg^{2+} or 0.04 mM Mg^{2+}. At various times the rates of synthesis of protein, RNA and DNA were determined by incorporation of: *a*, ^{3}H-proline (1.5 µCi ml^{-1}); *b*, ^{3}H-uridine (0.1 µCi ml^{-1}); or *c*, ^{3}H-thymidine (0.6 µCi ml^{-1}), respectively, into acid-insoluble material during 60-min incubations. ○, 0.04 mM Mg^{2+} ; ●, 0.84 mM Mg^{2+}.

to multiply until 48 h. In cultures with 0.11 mM Mg^{2+} or less in the growth medium, however, the growth rate showed a dependence on Mg^{2+} concentration. Mg^{2+} deprivation did not reduce the growth rate of these cells by simply decreasing their viability. Addition of 0.8 mM Mg^{2+} to the growth medium restored the increase of these cells to the maximum rate and allowed them to achieve the population density of cells in control cultures. This illustrates the possible potential of alterations in intracellular Mg^{2+} for the physiological regulation of cell growth.

As well as preventing serum-stimulation of cell growth, Mg^{2+} deprivation resulted in substantial decreases in the rates of synthesis of RNA and protein (Fig. 4). Twenty hours after the Mg^{2+} concentration had been decreased to 0.04 mM the rates of incorporation of ^{3}H-proline and ^{3}H-uridine were reduced 3.5-fold and 10-fold, respectively, from the level of control cells growing in 5% calf serum. Therefore Mg^{2+} deprivation seems not only to inhibit the rate of growth of CEF but also to inhibit their rate of macromolecular synthesis and presumably metabolism as a whole. This coordinate metabolic response of cells when the extracellular concentration of Mg^{2+} is reduced is also displayed on removal of serum or contact inhibition of growth[4]. Many agents that stimulate growth, such as serum, insulin and pH manipulation of the medium, seem to increase cellular functions in a coordinate manner[5]. We believe that the intracellular concentration of free Mg^{2+} has a central role in this coordinate metabolic response of animal cells to all these agents. Other divalent cations including Zn^{2+} (ref. 9) and Ca^{2+} (ref. 10) may have subsidiary roles.

In previous experiments, in which $Na_4P_2O_7$ or adenine nucleotides have been used to complex Mg^{2+} in the medium, similar effects on cellular metabolism have been noted and a model for coordinate control of cell metabolism has been proposed[1]. According to this model, intracellular Mg^{2+} is limiting in the formation of adenine nucleotide–Mg^{2+} complexes, essential substrates for transphosphorylation reactions. Transphosphorylation reactions, in turn, are viewed as the regulatory steps in metabolic pathways. This seems to be true in the glycolytic pathway, the one example where all the substrates and products of the pathway are readily assayed, since a selective activation of transphosphorylation reactions takes place when rates of glycolysis are increased[11,12]. The control of the intracellular level of free Mg^{2+} is brought about, in the context of this model, by changes in the competitive binding capacities of membranes and adenine nucleotides for Mg^{2+}. Because most of the cellular Mg^{2+} are presumably not free inside the cell but bound to membranes and other cellular constituents[13,14], serum and other agents that stimulate cell growth are postulated to alter membrane structure so as to release small amounts of membrane-bound Mg^{2+}. Chelation of Ca^{2+} in the culture medium by EGTA has been reported to inhibit cell growth in chick fibroblasts[10]: this might be the result of a competitive binding of Mg^{2+} and Ca^{2+} to membranes. The removal of sufficient Ca^{2+} from cellular membranes could result in a replacement by Mg^{2+} (ref. 13), resulting in a lower intracellular concentration of free Mg^{2+}. Indeed, it has been shown that the removal of Ca^{2+} from the medium markedly increases the sensitivity of cells to Mg^{2+} deprivation[15].

C1q production and secretion by fibroblasts

THE serum protein C1q is a subcomponent of the first component of the complement system. Combination of C1q with antigen–antibody complexes activates the other subcomponents of C1 (C1r and C1s) and sets in motion a series of events which results in activation of the entire complement system. The primary structure of C1q is unusual in that 40% of its amino acid sequence is composed of repeating X-Y-Gly triplets where X is often proline and Y often hydroxyproline or hydroxylysine, indicating a striking similarity to collagen[1,2]. It has also been proposed that these collagen polypeptide-like stretches in C1q associate in triple helical fashion[3]. Because of the similarities between these portions of C1q and collagen the present investigation was undertaken to determine whether C1q is synthesised by collagen-producing cells, namely fibroblasts.

Three fibroblast lines were used: human lung fibroblasts (from 13-week embryos) obtained from Gibco-Biocult (Paisley, Scotland); human skin fibroblasts (from 14–16-week embryos) and rat skin fibroblasts (from 16–18-day embryos) cultured in this laboratory. All cell lines were grown in air on glass slides in Petri dishes, or in 50-cm² glass culture flasks in HEPES buffered minimum essential medium containing 10% foetal calf serum, 2 mM glutamine, 0.25 mM ascorbate, 0.025 μM ferric nitrate and 50 units of penicillin and streptomycin ml^{-1}. All lines formed collagen fibres (demonstrated by reticulin staining) and contained prolyl hydroxylase. The cells used in all experiments had been subcultured four to six times.

C1q was localised in all three cell lines growing on glass slides, by an immunoperoxidase procedure[4] using a monospecific rabbit antiserum to human C1q (Hoechst Hounslow, England) and to rat C1q. As shown in Fig. 1, fibroblasts bind antibody to C1q avidly. This reaction (Fig. 1) is specific

Fig. 1 Localisation of C1q in cultured human fibroblasts. The cells were treated with monospecific antibody to human C1q and goat anti-rabbit IgG peroxidase conjugate by an immunoperoxidase procedure[5].
and indicates that C1q was present in the fibroblast cytoplasm of all cell lines as shown by the following control experiments. Fibroblasts overlaid by normal rabbit serum, or antiserum to C1q absorbed with pure C1q (ref. 5) or with fresh human or rat serum before processing through the immunohistochemical procedure failed to stain any of the fibroblast lines (Fig. 2). Antisera to C1q absorbed with heat-denatured normal serum (which renders C1q incapable of reacting with its antibody) did not abolish the reaction seen in Fig. 1. To exclude the possibility that antiserum to C1q cross reacts with collagen two further absorption experiments were done: previous absorption of antiserum to human C1q with neutral salt-soluble collagen failed to alter the reaction seen in Fig. 1; likewise antiserum to human C1q did not react in agar diffusion plates with a mixture of Type I and Type III procollagen purified from human embryonic skin[6]. On this evidence, therefore, it seems unlikely that anti-C1q was reacting with intracellular collagen antigen.
Fig. 2 Cells treated as in Fig. 1 except that normal rabbit serum was used instead of the antibody. No staining can be seen except that due to osmium tetroxide.

To determine whether C1q was also secreted by these cells, human fibroblasts from embryonic skin were grown to mid log phase under the same conditions in 50-cm² flasks. Each culture was then washed wtih 0.15 ml NaCl (2 × 5 ml) and incubated in 10 ml of serum-free minimum essential medium (supplemented as above) containing 2.4 μCi ml^{-1} of 3,4-^{3}H-proline (specific activity 20 mCi mmol^{-1}) for 60 min at 37 °C. The cell layers were then washed with 7 ml of 0.15 M NaCl and the medium and NaCl wash pooled and frozen at −20 °C until used. The cells were collected in 0.15 M NaCl, resuspended to 10^7 cells ml^{-1} in 0.1 M phosphate buffer (pH 7.2) containing 0.15 M NaCl and 0.01 M

Table 1 Immunoprecipitation of C1q from human fibroblast cultures and medium

Experiment	Aliquot (ml)	C1q precipitated per 10^7 cells* (c.p.m.)
Cell layer	0.15	1,407
Medium	2.5	4,225
	5.0	3,600

Human fibroblasts were cultured, pulsed with ^{3}H-proline, collected, sonicated and centrifuged as described in the text. Labelled C1q was precipitated from 0.15 ml aliquots of the cell supernatants by the addition of 0.1 ml of fresh human plasma (as carrier C1q) and rabbit antiserum to C1q. Labelled C1q was precipitated from aliquots of the medium in a similar way (see text).
*The number of counts in the control tubes (with normal rabbit serum) was 20% and 5% of that found in those containing anti-C1q for the cell layer and medium respectively. All results are the average of duplicate estimations.

EDTA, sonicated and centrifuged at 100,000g for 90 min. Fresh normal human serum (as carrier C1q) was added to the supernatant and to medium dialysed exhaustively against phosphate-buffered saline containing 0.01 M EDTA. Rabbit anti-human C1q was then added in threefold excess to the cell supernatants and medium, incubated at 37 °C for 30 min and overnight at 4 °C. In control tubes normal rabbit serum was added in the same proportion as the rabbit antiserum to C1q. The immunoprecipitates were collected, washed, dissolved in 1 N NaOH, and the radioactivity in each precipitate counted in Bray's solution. As shown in Table 1, C1q is present not only in the cells themselves but is also rapidly secreted by them such that in a 1-h pulse period approximately three times more labelled C1q is present in the medium than in the cell layer. It should be noted that the total amount of protein present in the immune precipitate was constant. For example, in the quantitation of C1q in medium (Table 1) the total amount of protein in each precipitate was 0.39 mg and 0.33 mg using 2.5 and 5 ml of medium respectively. This, therefore, excludes the possibility that the radioactivity which coprecipitated with carrier C1q was due to nonspecific precipitation or absorption of tritium to the precipitate itself. These data also argue against the possibility that the reaction product seen in immunohistochemical experiments (Fig. 1) was due to absorption of preformed C1q from the serum containing medium by fibroblasts.
Fig. 3 C1q localisation in the cells of a silica granuloma. Granulomas were produced on the backs of adult albino rats by the subcutaneous injection of 1.0% suspension of Dornetrop quartz in saline. The granuloma illustrated was excised 12 d after its production; frozen sections were cut and C1q localised by the immunoperoxidase procedure[5]. There is a positive reaction around nuclei (clear holes) in many of the cells in the granulation tissue. It is possible that some of the reaction product is also extracellular, but it is difficult to resolve this point with certainty in this type of preparation.

In an attempt to demonstrate the origin of C1q *in vivo* various rat organs (including foetal and neonatal organs) were examined by the immunoperoxidase procedure as described above. This screen was entirely negative. C1q production, however, could be demonstrated *in vivo* in fibroblasts surrounding a silica granuloma which had been produced in the subcutaneous tissue of adult Wistar rats as shown in Fig. 3.

These data indicate that fibroblasts *in vitro* synthesise and secrete C1q. It seems likely that C1q is also produced by fibroblasts *in vivo* at least in pathological conditions where fibroblasts are functioning at a much higher rate than normal, namely in a silica granuloma. This evidence does does not exclude C1q production by other cell types *in vivo* or *in vitro*[7]. It is noteworthy, however, that freshly isolated human blood lymphocytes, the only cells we have found

which do not contain prolyl hydroxylase *in vitro* (and presumably do not synthesise collagen) do not contain C1q when examined by the immunoperoxidase procedure.

These results also suggest that primary fibroblast cultures may serve as a useful cell source for studies of C1q biosynthesis.

Detection of α-foetoprotein in mouse liver differentiated hepatocytes before their progression through S phase

α-FOETOPROTEIN (AFP) is a serum protein present in large amounts during embryonic life and preserved in only nanogram quantities in adult mammals[1]. Increased levels of AFP are seen in adults in association with two forms of tumours —teratocarcinomas and hepatocarcinomas—and also during liver regeneration[2]. In early development AFP is synthesised in the yolk sac and in the liver[2,3] where it has been demonstrated by immunofluorescence in the majority of the hepatocytes[4]. Detailed aspects of AFP synthesis by hepatocytes, however, remain to be established. It has been suggested that it is synthesised by a definite population of hepatocytes[5], by one of the stages in their differentiation[6,7], or by liver cell precursors[8]. Sufficient data to decide between these alternatives are not presently available. We describe here the immunohistochemical localisation of AFP in regenerating mouse livers, in which DNA-synthesising cells have been identified by thymidine incorporation. AFP was found in a minority of adult differentiated hepatocytes, many of which had not progressed through S phase. Thus DNA synthesis is not a prerequisite for the induction of AFP synthesis in the adult liver.

Liver regeneration was induced by CCl_4 inhalation[9] in SWR or SWR/S mice (20–25 g). Serum AFP levels, as measured by immunodiffusion, increased significantly on day 2, reached a maximum on days 3–4 and had returned to basal levels by days 7–10. The centrolobular necrosis caused by CCl_4 resulted in practically all the remaining viable hepatocytes passing through one round of DNA synthesis, and a small fraction undergoing a second round. The most intensive DNA synthesis was found between 36 and 60 h and the duration of S phase in individual hepatocytes was 6.9 h (ref 10). These values were similar to those obtained in liver regenerating after partial hepatectomy, $S = 7.0 \pm 1.2$ h (ref. 11).

Mice with regenerating livers after exposure to CCl_4 were

Table 1 AFP in hepatocytes with and without thymidine incorporation

% Labelled nuclei in total hepatocyte population	67 (^{3}H 55 + ^{14}C 12)	54 (^{3}H 42 + ^{14}C 12)	0.6 (^{3}H 0.3 + ^{14}C 0.3)	82	38
% Labelled nuclei in AFP-positive hepatocytes	78 (^{3}H 69 + ^{14}C 9)	34 (^{3}H 22 + ^{14}C 12)	4 (^{3}H 2.3 + ^{14}C 1.7)	82	64
Number of nuclei of AFP-positive hepatocytes examined	486	185	175	335	257

Mice exposed to CCl4[4] (ref. 11) were injected intraperitoneally with radioactive thymidine in 0.1 ml saline as follows. Mouse 1: 1 µCi g^{-1} methyl-^{3}H-thymidine (19.8 Ci mmol^{-1}, Isotope, USSR) every 6 h, with 1 µCi g^{-1} methyl-^{14}C-thymidine (39 mCi mmol^{-1}, Isotope, USSR) 1 h before being killed. Mice 2 and 3: 1 µCi g^{-1} methyl-^{3}H-thymidine (20.5 Ci mmol^{-1}, Isotope, USSR) every 3–4 h, with 0.8 µCi g^{-1} methyl-^{14}C-thymidine (54 mCi mmol^{-1}, Prague) 1 h before being killed. Mice 4 and 5: 1 µCi g^{-1} methyl-^{3}H-thymidine (20.5 Ci mmol^{-1}, Isotope, USSR) every 3-4 h, the last injection being given 1 h before being killed. Mouse 1 was killed 48 h after exposure and mice 2-5 after 42 h. Livers were fixed in cold ethanol–acetic acid[12]. AFP was localised with indirect immunofluorescence on 3-µm liver sections, using monospecific antibodies to murine AFP isolated from rabbit anti-murine AFP antiserum. Staining could be completely blocked by the addition of an equivalent amount of purified murine AFP (ref. 12). AFP-positive hepatocytes were photographed, after which the sections were washed, dehydrated, dried and covered with photosensitive emulsion (N ii Chim Photo, Moscow, USSR). After exposure for 1 month at 4 °C the autoradiographs were developed and the sections stained with haematoxylin–eosin. The percentage of nuclei labelled with ^{3}H or ^{14}C, distinguishable by grain density, were determined after counting 2,000 hepatocyte nuclei. Using the immunofluorescent photographs all AFP-positive cells were identified on corresponding autographs and nuclei with ^{3}H or ^{14}C label counted.

repeatedly injected with methyl-^{3}H-thymidine and killed by decapitation on day 2, 1 h after the last injection of radioisotope. In some mice the final injection was of methyl-^{14}C-thymidine, as described in Table 1. The livers were fixed immediately in cold ethanol–acetic acid and embedded in paraffin[12]. AFP was localised in liver sections by indirect immunofluorescence, and the nuclei of the cells in which DNA synthesis had occurred were subsequently identified by autoradiography. Damaged cells which could accumulate serum proteins nonspecifically because of increased membrane permeability were detected by the immunohistochemical demonstration of the serum marker protein, IgG. Consecutive sections were used so that individual cells could be stained for both AFP and IgG (ref. 12).

Using indirect immunofluorescence we failed to find any AFP-containing structures in the liver sections of the control normal adult mice. For the first time several AFP-positive hepatocytes were found in the liver section 24 h after the CCl$_4$ poisoning. During day 2 their amount and intensity of fluorescence increased rapidly, reached a peak on day 3 followed by a sharp decline on the day 4. On day 2, when the experiment was terminated, AFP was present in not more than 3–5% of the hepatocytes, in both mono- and binucleate cells. Most AFP-containing cells were found in the region adjacent to the centrolobular necrosis (Fig. 1), although in some mice they were present in the periportal area. Intense IgG fluorescence was observed in the necrotic centrolobular cells, demonstrating their uptake of serum proteins, but was absent in the great majority of AFP-positive cells. It does not therefore seem that the latter have stained because of nonspecific uptake of AFP due to elevated serum levels. In the following analysis of thymidine
Fig. 1 AFP in the regenerating murine liver (mouse 1). Paraffin sections of liver fixed with ethanol–acetic acid and treated with rabbit anti-murine IgG serum (a) or purified rabbit antibodies anti-murine AFP (b and d) and FITC-conjugated donkey anti-murine IgG serum (Gamaleya Institute, Moscow, USSR). c and e, Autoradiographs of the areas ringed in b and d. Arrows show the same hepatocytes on the immunofluorescence photographs and on the autoradiographs. ^{14}C-label is easily distinguished from ^{3}H-label. b and c, Two nuclei of the AFP-positive hepatocytes are in S phase according to the intensive ^{14}C-label; two nuclei have no label. d and e, Two nuclei of the AFP-positive hepatocytes without label; two nuclei have incorporated ^{3}H-label and have progressed through S phase or all mitotic cycle. Magnification: a, b and d × 105; c and e × 225.

incorporation only IgG-negative, AFP-positive cells have been scored.

The percentage of labelled nuclei identified by autoradiography in the regenerating livers showed marked individual variation (Table 1). In all livers examined, however, numerous AFP-positive cells were seen without labelled nuclei (Fig. 1), as well as cells labelled in S phase with ^{14}C-thymidine 1 h before killing and cells labelled with ^{3}H-thymidine which had already progressed through S phase. The unlabelled cells comprised between 18 and 96% of the total of AFP-positive hepatocytes (Table 1).

The mice were injected with radioactive thymidine at intervals of 6 h (mouse 1) or 3–4 h (mice 2–5), that is less than the mean duration of S phase in these hepatocytes. As the thymidine was present in the circulation for at least 1 h after each injection, it is therefore unlikely that any DNA-synthesising cells could have escaped incorporation. Evidently AFP is localised in cells that have not yet commenced DNA synthesis during regeneration.

The time of appearance of the small number of AFP-positive hepatocytes, their quantity and intensity of fluorescence, all correlated directly with the changes in serum AFP measured. These observations, together with the failure of most AFP-positive cells to show nonspecific uptake of serum proteins, suggests that AFP is synthesised in these cells. If this is so, then the results show that AFP synthesis may be induced in the regenerating mouse liver in adult differentiated hepatocytes before the beginning of DNA synthesis. A similar suggestion has recently been made by Watanabe *et al.*[13], who have reported that serum AFP levels increase before the onset of proliferation in livers of rats treated with ethionine. In this context, it is worth noting that in an unrelated system (cultured erythroleukaemic cells), globin synthesis can be induced by butyric acid in the absence of cell division[14].

We thank Mrs M. D. Glishkina for assistance; Mrs V. S. Poltoranina, who started this work, Dr A. K. Yazova for monospecific antiserum to murine AFP and purified murine AFP; and the referee for comments.

Interaction of lighting and other environmental variables on activity of hypothalamo–hypophyseal–gonadal system

SINCE the pioneer study of Rowan[1], environmental lighting has been considered a predominant regulator of breeding activity in a variety of birds. A long daily photoperiod increases the levels of stored and circulating gonadotropins, and accelerates gonadal growth in Japanese quail[2,3], white-crowned sparrow[4], American tree sparrow[5], domestic pigeon[6] and mallard[7]. Other environmental variables such as temperature, rainfall and courtship are also known to influence breeding[8]. The nature of the endocrine response to temperature and rainfall is unknown, but the effect of male courtship on female endocrine systems has been studied extensively in ring doves (*Streptopelia risoria*). It increases the plasma levels of oestrogen[9], luteinising hormone[10] (LH) and progesterone[11], which in turn, induce sequential behavioural changes in the female that culminate in egg laying[12,13]. Using ring doves, I have investigated how environmental light and courtship interact to elicit the species-specific endocrine response. Since there is no significant change in testis size or weight during various stages of the breeding cycle of doves, this is not a suitable criterion for assessing the activity of the male endocrine state. Instead I used compensatory testicular hypertrophy, which is a response to environmental lighting in many species of birds, and investigated whether long daily photoperiod was required for this phenomenon in male ring doves, and whether courtship had any effect on this response.

Table 1 Description of experimental groups

Group	No. of males	Courtship condition	Daily light–dark (LD) cycle (h)
1	10	Isolation*	14:10
2	10	Isolation	8:16
3	10	Brief courtship†	14:10
4	10	Brief courtship	8:16
5	10	Breeding‡	14:10

* Males were housed individually in isolation rooms where they could hear, but not see, other birds.
† Males were introduced twice to a stimulus female in breeding cages that contained nest bowl and nest materials. Each exposure lasted 20 min. Sessions were spaced 1 week apart.
‡ Males were in a breeding cage that contained a stimulus female, nest bowl and nest materials throughout the 4-week experimental period.

Sixty reproductively experienced male ring doves from the indoor colony of the Institute of Animal Behavior, Rutgers University, were used. The colony is maintained under LD 14:10 controlled photoperiod and 21 ± 1 °C temperature. Fifty of the 60 birds were anaesthetised intramuscularly with equithesium (0.22 ml per 100 g), and the (larger) right testis of each was removed and weighed. The birds were then randomly assigned to one of five groups (Table 1), characterised in terms of daily photoperiod (LD 14:10 or LD 8:16) and the condition of courtship (isolation or breeding cage which contained a stimulus female). The remaining 10 doves were similarly anaesthetised, and both left and right testes removed and weighed. The stimulus females used for courtship condition were normal doves which showed sexual crouch, wing-flip and nest-coo[14].

Four weeks after dextral castration, all 50 males were laparotomised. The left testis (LT) of each was removed, and its weight expressed as a percentage of that of the right testis (RT). Since the LT weight of intact male doves kept under LD 14:10 was, on average, 80% that of the RT (Table 2), I considered LT $\geqslant 80\%$ of RT as evidence for compensatory

Table 2 Compensatory hypertophy of left testis after removal of right testis in the ring dove (*Streptopelia risoria*)

Group	Daily photostimulation/ courtship condition	No. of birds	Mean ± s.d. body weight (gm)	Mean ± s.d. right testis weight (mg)	Mean ± s.d. left testis weight (mg)	$\frac{\text{Left testis}}{\text{Right testis}} \times 100$ Mean	Range	Compensatory hypertrophy

‡ Measurements were taken 4 weeks after dextral castration.

hypertrophy. The results are summarised in Table 2. (1) Compensatory testicular hypertrophy occurred in birds under LD 14:10 (groups 1, 3 and 5), but not in birds kept isolated and under LD 8:16 (group 2); (2) LT weights of birds in group 2 averaged only 60% that of RT, indicating that the LT had regressed rather than augmented. (An histological study showed an increase in size of seminiferous tubules, Leydig cells and sperm count in the augmented testis.)

These results, together with the finding that LD 8:16 caused testicular regression in ring doves (unpublished) and the fact that other species of birds show a decline in plasma LH level[3-5], demonstrate that long daily photoperiod is an important regulating factor for the feedback function of the hypothalamo–hypophyseal–gonadal system. Short exposure to courtship (two pairing sessions with stimulus females for 20 min each and 1 week apart) however, resulted in good testicular hypertrophy in male doves kept under LD 8:16 (group 4). The stimulatory effect of courtship on male doves does not seem to increase with increased duration of exposure to stimulus females. There was no apparent difference in LT weight among birds kept under LD 14:10, regardless of whether the birds were isolated or exposed to stimulus females (groups 1, 3 and 5). Thus, it seems that the combined effects of courtship and lighting on the hypothalamo–hypophyseal–gonadal system are guided by an adaptive change of endocrine state for the species, rather than simply a mathematical sum of respective environmental effects.

Two brief exposures to a stimulus female (20 min each and 1 week apart, group 4) affected males in a manner comparable with that of 6 h additional daily photoperiod for 4 weeks (group 1); this makes the stimulatory effect of female courtship on compensatory testicular hypertrophy even more significant. This is equally true of the effect of male courtship on female systems.

Under long photoperiod (LD 14:10), follicles of female ring doves took 20 weeks to develop from 2–3 mm to 8–9 mm in diameter, and they then became atresic. In contrast, when paired with male doves in breeding cages, female ring doves of similar ovarian stage (follicle size 2–3 mm) took only 7–11 d to develop large follicles (14–15 mm) which subsequently ovulated and oviposited (unpublished).

In male and female Japanese quail, although long photoperiod increases gonadotropin-releasing factor in the posterior basal hypothalamus area[3,15], there is no direct evidence to suggest a similar effect of courtship stimulation on releasing factor by the hypothalamus. In my study, compensatory hypertrophy in birds kept under LD 8:16 and exposed to stimulus females twice (group 4), strongly suggests that courtship stimulates either: gonadotropin synthesis, gonadotropin release, or the sensitivity of the pituitary to gonadotropin-releasing factors. I favour the second possibility in view of the following findings in the

Japanese quail: (1) Long daily photostimulation results in gonadal development[3] and hypothalamic gonadotropin-releasing activity[15]; and (2) a change of daily photoperiod from LD 14:10 to LD 8:16 results in a lower level of plasma LH and testicular regression, but a higher level of pituitary LH; these events occurred within 6–16 d following the onset of short photoperiod[3]. Similarly, in male golden hamsters, exposure to non-stimulatory photoperiod does not alter the increased pituitary LH and follicle stimulating hormone (FSH) content after castration, whereas the serum levels of LH and FSH decline substantially[16].

On the basis of these findings, it seems that environmental photoperiod affects the synthesis as well as release of gonadotropins; the releasing mechanism being more responsive to an immediate photoperiodic change than the synthesis, whereas synthesis (and/or store) is regulated by a long term photoperiodic change and endogenous feedback system. The failure of the hypertrophy response in birds kept in short light regimes (group 2) is thus a result of the cessation of gonadotropin release in response to the short photoperiod. Gonadotropin release can, however, be induced by other environmental stimulation (such as a female stimulus, warm temperature, rainfall and so on), which results in the hypertrophy seen in group 4 birds kept in short light regimes. The release is possible since synthesis (and/or store) of gonadotropin is not affected by immediate photoperiodic change.

A discontinuous relationship between the acetylcholine-activated channel conductance and temperature

SINCE the introduction of acetylcholine (ACh) 'noise' analysis[1,2], it has been shown that several manipulations affect ACh-receptor molecular events[3-5]. The ACh receptor is an integral membrane protein and is therefore intimately associated with surrounding membrane lipids. We have begun experiments using embryonic chick muscle in culture to determine whether surrounding lipids affect the function of the ACh receptor. As a first step, we have analysed ACh current noise to determine the temperature dependence of the mean single channel conductance ($\bar{g}_o$) and open time ($\bar{t}_o$).

At frog endplates $\bar{t}_o$ is gradually prolonged as the temperature (T) is lowered but $\bar{g}_o$ remains essentially unchanged. We observed a similar relation between $\bar{t}_o$ and T in cultured chick muscle, but in contrast to results obtained in amphibia, $\bar{g}_o$ was markedly decreased at low temperatures. Moreover, there was a marked discontinuity in the relation between T and $\bar{g}_o$. A clear 'transition' temperature was observed at ~ 20 °C which suggests that $\bar{g}_o$ may depend on the 'fluidity' of the receptor microenvironment.

ACh-induced transmembrane currents were recorded in voltage clamped large spherical muscle cells (Fig. 1). Such spheres or 'myoballs' are more suitable than elongated cylindrical muscle fibres for voltage clamp analysis. The interior of each myoball is isopotential and the membrane potential can be held constant, even in the face of large ACh responses (up to 200 nA). Myoballs are 'normal' in the sense that they are extremely sensitive to ACh and they contract.

Control of membrane potential was achieved with two intracellular electrodes—one for measuring the membrane potential and the other for supplying the feedback current required to hold the membrane potential constant. The microelectrodes had a resistance of 3–10 MΩ when filled with 3 M KCl. A microelectrode filled with ACh was located 50–100 μm away from the cell and ACh was ejected by prolonged, positive pulses. Temperature was controlled by perfusing ethanol (+ 60 °C to − 30 °C) between the glass bottom of the recording chamber and the objective of the inverted microscope. In most

experiments, the membrane potential was clamped at − 80 mV. Feedback currents were stored on magnetic tape (frequency response 0–1,250 Hz).

A typical ACh response is shown in Fig. 2a. The horizontal bar indicates the duration of the ACh pulse. The lower trace is a low gain d.c. recording of the membrane ionic current and the upper trace is a parallel, high gain filtered (bandpass 1–200 Hz) recording which shows the fluctuations or noise of the ACh-induced current. In this example, the maximum inward current produced by ACh was 100 nA.

ACh responses were analysed with a PDP/8e computer. The single-channel conductance, $\bar{g}_o$, was estimated from the slope

a

b
Fig. 2 ACh-induced membrane currents in voltage clamped myoballs. *a*, A 15-s long pulse of ACh (horizontal bar) results in a large increase in mean membrane current (lower trace: a low-gain d.c. recording) and an increase in current fluctuations (upper trace: a parallel high gain filtered channel). The membrane potential was clamped to −95 mV. The slow rise of the response reflects the time required for ACh to diffuse from the ACh pipette located 50 μm away. Vertical bars: 3 nA upper trace, 100 nA lower trace. *b*, Digitalised, 2-s long, samples of ACh current fluctuations (noise). The upper trace shows control fluctuations in the absence of ACh. The steady holding current is defined as zero. ACh responses obtained at 23 and 9 °C are shown in the middle and lower traces respectively. The mean ACh current was 75 nA at both temperatures. Note that at 9 °C, high frequency components are less prominent and that the amplitude of the noise is decreased. Vertical bar, 2 nA; horizontal bar = 250 ms.

Fig. 1 A large chick myoball. Spheres were obtained by adding mononucleated muscle precursor cells dissociated from 11-d pectoral muscles to Petri dishes coated with Sylgard (Dow Corning). The cells did not attach to this surface, and over the next 2–3 d muscle precursor cells fused with one another in suspension to form multinucleated 'myoballs', 50–120 μm in diameter. For electrophysiological experiments, myoballs were allowed to settle on collagen-coated glass coverslips which were then placed in a chamber on an inverted phase contrast microscope. Smooth surfaced myoballs could be easily distinguished from aggregates of fibroblasts which had a cobblestone-like appearance. Bar = 100 μm.

of the linear relation between the variance of current fluctuations and the mean membrane current. The mean channel open time, $\bar{t}_o$, was estimated from the spectral density function, $S(f)$; $\bar{t}_o = 1/2\pi f_c$ where f_c is that frequency at which $S(f)$ is reduced by half[1,2,6]. At 37 °C, when the membrane potential was set between −70 and −95 mV, $\bar{g}_o$ ranged between 25 and 45 pmho, and $\bar{t}_o$ between 2.5 and 4.0 ms.

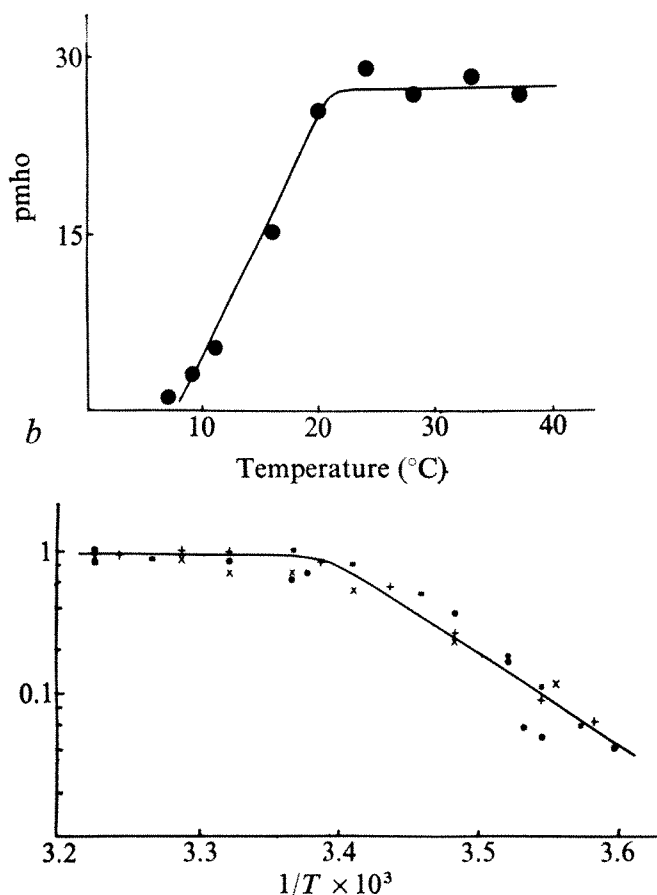
Figure 2b shows digitalised records of control or background noise and ACh-induced noise at two temperatures (sampling rate: 500 s⁻¹). As reported in previous studies in amphibia, lower frequency components predominate at the lower temperature. In this example, $\bar{t}_o$ increased from 7.2 ms at 23 °C to 16.1 ms at 9 °C. In these chick cells, $\bar{t}_o$ increased continuously as T was lowered from 37 to 7 °C. In addition, Fig. 2 shows that the amplitude of the current fluctuations is markedly decreased at 9 °C, even though the mean ACh-induced current is the same at the two temperatures. Estimates of $\bar{g}_o$ in this cell decreased


Fig. 3 Temperature dependence of single channel conductance $\bar{g}_o$ in chick myoballs. *a*, Nine ACh responses elicited in the same cell at different temperatures between 7 and 37 °C are shown. The relationship between $\bar{g}_o$ and temperature is discontinuous; a sharp transition is observed at ~ 20 °C. *b*, Arrhenius plot of normalised data obtained in four different myoballs. The activation energy (E_a), calculated from the equation $\log g_o = C - (E_a/2.3R)(1/T)$ (R = gas constant, T = absolute temperature, and C = a constant) increases from virtually 0 above 20 °C to 30 kcalorie mol^{-1} below this critical temperature.

in this report. The degree to which an ACh-activated channel opens may depend on the flexibility of fatty acids in its micro-environment. It may be significant that the membranes of poikilothermic animals (in which $\bar{g}_o$ remains nearly constant between 10 and 23 °C) contain relatively more unsaturated fatty acids which 'melt' at a lower temperature[9]. The fact that no clear break was observed in the relation between $\bar{t}_o$ and T may simply mean that different molecular processes regulate $\bar{t}_o$ and $\bar{g}_o$.

It should be possible systematically to modify the membrane lipids of rapidly growing muscle cells by adding specific fatty acids to a culture medium made up with delipidated serum[10]. The relationship between $\bar{g}_o$ and membrane fluidity might then be defined in more detail. In addition, changes in regional and/or overall membrane fluidity may alter the degradation of ACh receptors or their insertion into, or distribution within, the membrane.

We thank C. F. Stevens for help with the voltage clamp amplifier and S. M. Schuetze for the computer programming. This investigation was supported in part by a Fogarty International Research Fellowship and Yad Avi Ha-Yishuv Foundation, Israel (Y.L.), and by a USPHS Research Grant from the NIH (G.D.F.).

from 31 pmho at 23 °C to 7.6 pmho at 9 °C. A comparable or larger decrease in $\bar{g}_o$ was obtained whenever the temperature was lowered to 10 °C, and in each case the change in $\bar{g}_0$ was completely reversed on rewarming the preparation. This dramatic effect cannot be explained by a negative shift in the ACh reversal potential (measured by ACh application at membrane potentials between -80 and $+30$ mV) which remained fixed at ~ -5 mV between 37 and 5 °C.

In contrast to the continuous relationship between $\bar{t}_o$ and T, there was a clear discontinuity in the relation between $\bar{g}_o$ and T in every case examined (Fig. 3). There was no significant decrease in $\bar{g}_o$ as T was lowered from 37 to 20 °C. As T was lowered further to 5 °C, however, there was a nearly tenfold decrease in $\bar{g}_o$. An Arrhenius plot including points from four myoballs is shown in Fig. 3*b*. From the slope it can be determined that the activation energy for those factors or events which determine the magnitude to which an ACh channel can open is increased by 30 kcalorie mol^{-1} at ~ 20 °C.

A transition temperature has been observed in studies of other membrane proteins where enzyme activity, or transport or mobility within the lipid bilayer were assayed[7,8]. It is thought that a change in membrane fluidity occurs at the critical temperature. That is, above the critical temperature, the phospholipid fatty acid side chains are flexible and the interior of the membrane is fluid; below the critical temperature, movements of fatty acid side chains are restricted and the membrane core is more solid. It is plausible that the same mechanism explains the discontinuous relation between $\bar{g}_o$ and T described

Long term potentiation is accompanied by a reduction in dendritic responsiveness to glutamic acid

Hippocampal synapses show an unusual degree of physiological plasticity. Relatively modest levels of repetitive stimulation cause considerable enhancement in subsequent responses to single pulse stimulation, and this potentiation lasts for hours and even days[1–6]. These findings, which have now been replicated in several laboratories, have aroused much interest, first because they seem to represent an excellent starting point for the analysis of synaptic plasticity in mammalian brain, and second, because their rapid development and persistence suggest that they may be related to processes involved in behavioural plasticity. The studies reported here represent an attempt to analyse the mechanisms underlying physiological plasticity in the hippocampus, in particular the locus and anatomical specificity of the effect. The change in magnitude of response which occurs after repetitive stimulation could reflect either presynaptic or postsynaptic adjustment. If the latter were the case, the change might involve a particular dendritic region innervated by the stimulated input, or alteration in the status of the entire postsynaptic neurone. Seeking data relevant to these questions, we have measured the effects of glutamic acid applied iontophoretically to different levels
Fig. 1 Schematic representation of the transverse hippocampal slice and the experimental electrode arrangement. Extracellular unit activity and evoked potentials were recorded from the CA 1 pyramidal cell somal layer as indicated. The separate multi-barrelled iontophoresis electrode could be placed at any point in the apical and basal dendritic zones of a particular neurone for the purpose of glutamic acid ejections. Schaffer collateral–commissural stimulation was accomplished through a bipolar electrode placed along the tract at the CA 1–CA 2 border.

of the dendritic trees of the pyramidal cells before and after potentiation of the extracellular postsynaptic response.

Glutamate more or less universally excites neurones[7-9] and it is generally thought that it does this by depolarising the cell through an action on sodium and possibly potassium channels[9]. We reasoned that if potentiation produced a lasting change in the membrane properties of the post-synaptic cell, this might cause changes in that cell's response to discrete applications of glutamic acid. Furthermore, if the postsynaptic effect were generalised, that is, not restricted to the dendritic area affected by the driven input, then an altered response would be found to glutamic acid applied anywhere in the dendritic field. To test these possibilities we have used *in vitro* transverse slices of rat hippocampus, prepared and maintained as described before[10]. The experimental arrangement is described in Fig. 1. Briefly, a bipolar stimulating electrode (62 μm wire) was placed on the Schaffer collaterals (the fibre connection consisting of collateral axons from the CA 3 field to the CA 1 field of pyramid cells (Fig. 1)) and a recording micropipette was guided into the layer of pyramidal cell bodies, the proximal dendrites of which receive the Schaffer input. The recording electrode was advanced until it was located next to a spontaneously active cell. The electrode recorded both the spike activity of the "isolated" cell and the characteristic field potential elicited by stimulation of the Schaffer collaterals. This response is a simple monophasic positive wave when threshold stimulation (4–7 V) is used; at slightly higher voltages a sharp negative deflection is superimposed on the wave (Fig. 2). This negative wave has been shown by Andersen and associates to be an envelope of synchronously driven cell spikes, that is, in their words, a "population spike"[11]. We used this response as our index of the magnitude of the postsynaptic response. A third multibarrelled electrode was used for iontophoretic application of 0.2 M L-glutamate to various regions of the pyramidal cells' dendritic field. Only a single CA 1 dendritic locus was tested in each slice. When the recording and electrical stimulation electrodes were in position the iontophoresis electrode was lowered into the chosen region of the dendritic field while glutamate was ejected at 20–30 nA until the recorded cell was vigorously, though not maximally, driven. The iontophoresis current was then lowered until a short latency and stable response were obtained for a 10-s test period. When all three electrodes were in position the experiment was

begun (usually at about 2 h after preparation of the slices). A constant current source was programmed to pulse the glutamate on to the CA 1 dendrites for 10 s every 40 s for 3–5 min. During this time averages of 10 field potentials were collected in response to stimulation of the Schaffer collateral bundle. Stimulus pulses were applied once every 5 s at a voltage adequate to elicit a small (less than 1-mV) population spike. Then 15-Hz tetanic stimulation was delivered for 15 s, after which iontophoretic applications were conducted as before. Field potentials were again collected and averaged 1, 4, 7, 12, and 20 min after 15-Hz stimulation —these were elicited by the same voltage and frequency as used before the conditioning train.

Twenty-two slices were tested by this procedure. Four of these did not show potentiation of the "population spike"
Fig. 2 The upper traces are computer averages of the field potential recorded by the pipette located in the cell body layer before (Pre) and 1, 5 and 10 min after a 15-Hz, 15-s train of stimulation pulses (denoted by S) to the Schaffer collateral system. The field potential and the population spike, the negative deflection riding on the positive wave, were greatly enhanced by the tetanising stimulation. The lower traces are records of the rate of spike discharges of a small population of pyramid cells, recorded by the same microelectrode used to collect the field potentials, in response to a 10-s iontophoretic pulse (25nA) of glutamic acid applied in apical dendritic field 200 μm away from the cell layer. Repetitive stimulation caused a decrease in the excitation produced by the amino acid.

after the conditioning pulses and in two others the degree of response facilitation was quite modest. In the rest of the slices, the "post-tetani" responses were at least twice the amplitude of the control responses. In a few slices from this last group the potentiation was transient and the response was clearly returning towards baseline by the end of the test runs.

The effects of the tetanising stimulation on the unitary response to glutamic acid were consistently the reverse of that displayed by the field potential. In addition it seemed that the nature and degree of the decrease in response to glutamic acid were related to the duration and magnitude of field potential potentiation. In slices which showed a potentiated response the excitation elicited by glutamic acid was reduced by at least 25%. The effect appeared within 30 s of the termination of the conditioning train and

generally persisted throughout testing. Furthermore, in those slices in which the potentiation was transient the reduction of the response to glutamic acid gradually dissipated (Fig. 3).

As mentioned, two slices showed very modest potentiation and in these cases the suppression of glutamic acid excitation was less than 25%. Finally, three of four slices which did not potentiate also did not exhibit any change in responsiveness to iontophoretically applied glutamic acid. The one exception demonstrated a very slight and transient reduction. Table 1 summarises these points. In 10 of the slices we used a second train of conditioning pulses and measured the effects of this on the response of the pyramidal cells to glutamic acid. The results of these tests were comparable with those obtained after the first tetanus: that is a strong potentiation ($N=6$) was accompanied by a reduction in responsiveness to glutamic acid, whereas absence of potentiation ($N=4$) was correlated with essentially no change in iontophoretically induced unitary excitation (Table 1, bottom).

Glutamate has been found (ref. 12 and unpublished results of V.K.G., H. J. Spencer, C. W. Cotman and G.S.L.) to excite pyramidal cells more or less independently of where it is applied to the dendritic tree, and our study confirmed this. More pertinent to our findings, depression of glutamic acid-induced excitation was found even when the amino acid was applied outside the region of Schaffer collateral innervation (to the basal dendrites), or to the apical dendritic tips in the zone of entorhinal innervation (Fig. 1).

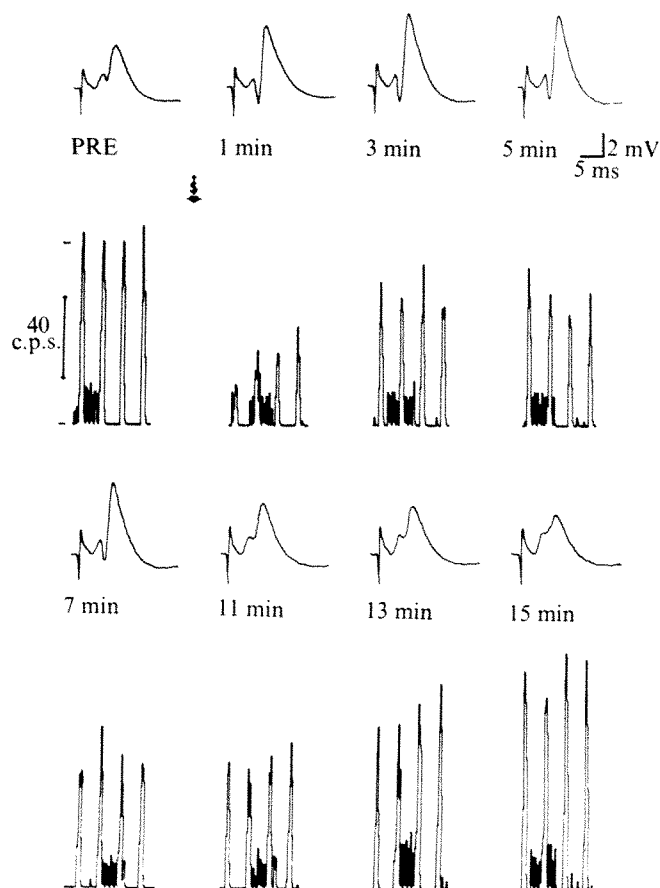
Fig. 3 An example of post-tetanic potentiation which did not persist for more than 15 min after the 15-Hz, 15-s conditioning train (S). Note the reduction of glutamic acid effect while the field response was in a potentiated state, and the return of driving to preconditioning levels as the evoked potential decreased to baseline levels. All variables are the same as in Fig. 2.


Table 1 Potentiation and response to glutamate

		Relative degree of potentiation			
		0	1	2	
Relative depression of responses to glutamate	0	3	—	—	
	1	1	2	1	First
	2	—	—	8	test
	3	—	—	5	
	0	2	—	—	
	1	1	1	—	Second
	2	—	—	3	test
	3	—	—	3	

The figures are the numbers of slices displaying the noted degree of potentiation (0, no change; 1, less than 100% increase in population spike within 1 min of the end of stimulation train; 2, greater than 100% increase in population spike in this time frame) and a particular degree of reduction in response to iontophoretic application of glutamic acid (0, no change; 1, 10–25% reduction of firing rate; 2, 25–40% reduction in firing rate; 3, greater than 40% reduction). First and second tests are explained in text.

These results indicate that tetanic stimulation produces a lasting change in responsivity of the postsynaptic membrane and that this change is generalised to the entire neurone. The similarity in degree and time course of the alteration in glutamic acid responsiveness and the size and duration of potentiation suggest that these two phenomena are related. Postsynaptic depression after tetani has been reported in the peripheral nervous system (for example ref. 13) but the rapid development and persistent nature of the effects reported here make it unlikely that comparable processes are involved. Speculation as to the physiological nature of the changes responsible for the altered glutamic acid response will be more profitable after completion of intracellular recording studies which are currently in progress.

Inhibitory postsynaptic current in voltage-clamped crayfish muscle

THE current–voltage relationship provides important information about the mechanism of ionic permeation through membranes. In excitatory synapses the relationship between membrane potential and excitatory postsynaptic current (e.p.s.c.) has been extensively studied using the voltage-clamp method[1-6]. In the frog endplate it has been shown that the e.p.s.c. was smaller than would be expected from a linear

relationship during hyperpolarisation of the membrane[3,4]. On the other hand, after iontophoretic application of acetylcholine, the synaptic current increased more than expected at hyperpolarised membrane potentials[7]. In investigating the current–voltage relationship it is important to measure the current on both sides of the equilibrium potential. Inhibitory postsynaptic current (i.p.s.c.) is more suitable for this purpose, because the reversal potential is near the resting potential and so the current–voltage relationship on both sides of the reversal potential can be measured using relatively small potential changes. Little attention has been paid, however, to inhibitory postsynaptic membranes, possibly because the inhibitory synapses are distributed diffusely over the surface of the cell or situated on dendrites remote from the cell body where the electrical changes are measured. In these conditions it is difficult to measure accurately the current–voltage relationship. We have cannulated the opener muscle of the claw in the crayfish (*Cambarus clarkii*) using a stainless steel wire, the membrane potential being clamped at various levels as described previously[6]. Although the inhibitory synapses are distributed over the whole surface of the muscle fibre, the space clamp condition of the muscle fibre was maintained well using this technique. We have found that the relationship between membrane potential and i.p.s.c. was highly nonlinear on hyperpolarisation of the membrane.

Fig. 2 Relationship between clamped membrane potential and amplitude of i.p.s.c. *a*, Peak amplitude of i.p.s.c. produced at 16 Hz; *b*, plateau level of i.p.s.c.s produced at 107 Hz. Inside current expressed as positive.
Fig. 1 Inhibitory postsynaptic current (i.p.s.c.) recorded at various membrane potentials. *A*, Superimposed i.p.s.c. at stimulation rate of 16 Hz: *a*, −37 mV; *b*, −46 mV; *c*, −57 mV; *d*, −79 mV; *e*, −90 mV. Upward deflection indicates the inside current. *B*, Train of i.p.s.c.s produced at 107 Hz: *a*, −47 mV; *b*, −60 mV; *c*, −76 mV; *d*, −99 mV; *e*, −109 mV.

The inhibitory axon was dissected at the melopodite and stimulated using a pair of silver electrodes. Inhibitory stimulation produced the inwardly directed i.p.s.c. at hyperpolarised membrane potentials (Fig. 1*A*, *d* and *e*). Although the time course of the i.p.s.c. was rather variable from fibre to fibre, the current reached its peak within ∼ 4–5 ms and thereafter decayed almost exponentially with a time constant of 10–20 ms (total duration up to 50 ms). On depolarisation of the membrane, the amplitude of the i.p.s.c. decreased and the current reversed its sign at about −60 mV (Fig. 1*A*, *c*). The peak time and falling phase of i.p.s.c. at depolarised membrane potentials (downward deflections in Fig. 1*A*, *a* and *b*) were slightly longer than those at hyperpolarised membrane potentials. The time constant of the falling phase was 15.6 ± 5.1 ms at about −100 mV and 21.3 ± 6.0 ms at −40 mV (mean ± s.d., $n = 8$).

The time course of changes in i.p.s.c. was much slower than that of the e.p.s.c. recorded from the same muscle; the peak time of e.p.s.c. being about 2–3 ms and the time constant of the falling phase being 3.3 ± 1.1 ms at −100 mV. On repeated stimulation of the inhibitory axon, the falling phases of the i.p.s.c. summed up to a plateau (Fig. 1*B*). Such a summation was, however, not manifest in the e.p.s.c. (ref. 6.)

The peak amplitude of a single i.p.s.c. (Fig. 2*a*) and the plateau level of repeated i.p.s.c.s (Fig. 2*b*) were plotted against the clamped membrane potential. The synaptic current–membrane potential relationship was almost linear for the depolarised membrane up to −30 or −15 mV. When the membrane potential was hyperpolarised by about 20–30 mV from the reversal potential, however, the relationship deviated from linearity and the i.p.s.c. reached an approximately limiting value (Fig. 2*b*). This is different from observations of e.p.s.c., which increased almost linearly up to −120 to −150 mV (ref. 6). Since the i.p.s.c. is carried by Cl⁻ (ref. 8), the outwardly directed Cl⁻ flux seems to be limited at hyperpolarised membrane potentials. An essentially similar relationship was observed when GABA was added to the bath solution, and the increase in the membrane current at various membrane potentials measured using the voltage-clamp technique.

Since the time course of changes in i.p.s.c. became faster on hyperpolarisation of the membrane, nonlinearity may be explained by the voltage-dependent rate constants for the opening and closing of the conductance channels[9]. In many cases, however, the current–voltage relationship deviated more markedly from linearity than would be expected from the dependence of rate constants on voltage. Qualitatively similar nonlinearity—by the depolarisation of the membrane—has been observed at acetylcholine receptors in the frog endplate[7] and electroplaque[10]; these could be accounted for using the above hypothesis.

α-adrenergic receptors and pacemaker current in cardiac Purkinje fibres

In recent years, membrane phenomena in cardiac fibres have been analysed with increasing accuracy, by the use of electronic feedback. Ionic transmembrane currents have now been measured and analysed for their rectifier properties, their time constants and their activation ranges. One of the current components analysed in much detail is the pacemaker current in cardiac Purkinje fibres. Evidence is now accumulating that this and other current systems are related to adrenergic receptors. Strong evidence has been put forward that this current is dependent on β-adrenergic receptors. In this paper we report results of tests carried out to investigate the involvement of α-adrenoceptors in controlling this process and to show that they are not directly involved.

The pacemaker potential in cardiac Purkinje fibres is generated by a time-dependent deactivation of a slow outward current, i_{K2}[1,2], which allows the time-independent steady-state inward current to depolarise the membrane. Using the formalism of Hodgkin and Huxley[3] this current component is described in the following way

$$i_{K2} = \overline{i_{K2}} \times s \qquad (1)$$

where $\overline{i_{K2}}$ is the instantaneous or fully activated current–voltage relationship and s is a dimensionless variable which controls the degree of activation of i_{K2} and which follows first-order kinetics

$$ds/dt = \alpha_s(1-s) - \beta_s \times s \qquad (2)$$

α_s and β_s are the rate constants which are voltage dependent only. The steady-state degree of activation of i_{K2} was measured in voltage clamp conditions[2,4] as the amplitude of the current tail on the return to the holding potential. Since the holding potential is unchanged, $\overline{i_{K2}}$ must be the same and equation (1) can be modified

$$i_{K2} \propto s \qquad (3)$$

Adrenaline shifts the S-shaped curve relating the steady-state degree of activation and the membrane potential (s_∞) as well as the reciprocal of the time constant ($\tau^{-1} = \alpha_s + \beta_s$) in the depolarising direction[5-9]. The instantaneous current–voltage relation,
Fig. 1 Effect of methoxamine $(4 \times 10^{-5}\,\mathrm{g\,ml^{-1}})$ on voltage clamp currents in sheep Purkinje fibres. The Tyrode solution contained the following concentrations of ions (mM): Na^+ 148.3, K^+ 4, Ca^{2+} 1.8, Mg^{2+} 0.5, Cl^- 144.6, HCO_3^- 12, PO_4^{3-} 0.35, glucose $2\,\mathrm{g\,l^{-1}}$. Each of the current records shows the response to 30 mV depolarisation and to 10 mV hyperpolarisation from a holding potential of $-70\,\mathrm{mV}$. Note that the time-dependent current (i_{K2}) is changed neither with methoxamine nor with methoxamine plus adrenaline. The instantaneous current jump following depolarisation vanishes with methoxamine and is restored by adding adrenaline in the presence of methoxamine.

however, is altered neither by adrenaline[6,8], nor by racemates[8], nor optical isomers[9] of various β-receptor blockers. It was previously thought that in heart muscle only β-adrenergic receptors are present and thus it was rather surprising when Cranefield et al.[10] reported evidence for α-receptors in Purkinje fibres. Since agents specifically blocking β-adrenergic receptors shift the kinetics of i_{K2} back in the negative direction[5-9] the question arose whether i_{K2} may also be influenced by drugs stimulating alpha receptors. Tsien[6] found no detectable shift of the s-kinetics using phenylephrine $(10^{-5}\,M)$ and propranolol $(10^{-6}\,M)$, a well known β-receptor-blocking agent with strong local anaesthetic properties. Since in this (single) experiment two drugs were used—one of them (propranolol) with appreciable side-effects—it seemed appropriate to extend these studies and to use methoxamine $(4 \times 10^{-5}\,\mathrm{g\,ml^{-1}})$[10], a very selective α-receptor-stimulating agent with β-receptor-blocking activity[11] (provided by the Deutsche Wellcome GmbH).
Fig. 2 Relationship between the steady-state degree of activation (s_∞) of i_{K2} and the membrane potential. ○, Control; △, methoxamine $(4 \times 10^{-5}\,\mathrm{g\,ml^{-1}})$; ▲, adrenaline $(10^{-6}\,\mathrm{g\,ml^{-1}})$ plus methoxamine. Note that unlike the treatment with β-receptor-stimulating agents methoxamine as an α-adrenergic substance does not change the voltage dependence of s_∞. Nor does adrenaline cause any shift in the presence of methoxamine.

In our experiments chart records of Purkinje fibre action potentials showed that a fibre was slightly depolarised with methoxamine. For an example in control conditions the resting potential amounted to -76 mV and decreased during the administration of methoxamine to -72 mV. Thus, it is not possible to tell whether the diminution of the amplitude of the action potential (and probably also of the rate of rise) observed after treatment with methoxamine was due to depolarisation only or whether this drug also reduces the availability of the excitatory sodium current at a particular membrane potential.

Weidmann's[12] h_∞ curve predicts a reduction in the rate of rise by about 25% due to a depolarisation of the order we observed. But in spite of the slight depolarisation, the time course of the pacemaker potential was essentially unchanged.

Figure 1 shows the membrane current changes as responses to long-lasting depolarising and hyperpolarising clamp pulses. There was no measurable change in the time-dependent currents. The only alteration was in the non-time-dependent background current called i_{K1} (refs 2 and 13). This instantaneous current changed in the inward direction—that is, the outward current jump after depolarisation became negligible when methoxamine was present; during and after hyperpolarisation an increase in i_{K1} could hardly be detected. But a decrease in an instantaneous outward current would be expected to depolarise the fibre. This current change was reversed when adrenaline was added together with methoxamine.

Figure 2 shows the relationship between the steady-state
Fig. 3 Voltage dependence of the rate of change of i_{K_2} measured in terms of reciprocal of the time constant (τ^{-1}) of current change. Symbols as in Fig. 2.

degree of activation of i_{K_2} and the membrane potential measured as the amplitude of the current tail on return from various clamp potentials to the holding potential. This curve was shifted neither with methoxamine nor with methoxamine plus adrenaline (Fig. 2).

The absence of any shift in s_∞ by adrenaline in the presence of methoxamine was probably a consequence of the β-receptor-blocking activity of this drug[11].

The time constant of i_{K_2} at potentials less negative than the pacemaker region of potentials is determined by a procedure called the 'envelope test'[2] in which the duration of the clamp to a particular potential is progressively shortened, thereby switching on i_{K_2} to various degrees.

The time constant of i_{K_2} was identical at a particular potential whether determined in control conditions, in the presence of methoxamine or in the presence of methoxamine plus adrenaline. τ_s was measured as the amplitude of current tails on return to the holding potential following clamps to -36 mV of various durations and was found to be 106 ms. Nor is there any shift in the U-shaped curve relating the reciprocal of the time constant and the membrane potential (Fig. 3).

The kinetics of i_{K_2}—or the second factor in equation (1)—are related to the electric field at the membrane and thus the voltage dependence of the kinetics may be modified by altering the amount of electric charges at the inner or outer edge of the

Fig. 4 Instantaneous current–voltage relationship of i_{K_2}. This relationship is obtained from the quotient of the amplitudes of i_{K_2} during and following voltage clamp pulses to various levels. The 'rectifier ratio' obtained in this way is then multiplied by the amplitude of s_∞ measured at the same holding potential, resulting in the value of the 'rectifier function', $\overline{i_{K_2}}$. The absolute magnitude of i_{K_2} is altered neither with methoxamine nor with methoxamine plus adrenaline and the rectifier properties are unchanged with either condition. Symbols as in Figs 2 and 3.

Rectifier function
membrane. The findings described here show that stimulation of α-receptors does not influence the electric field near the i_{K_2} channel.

The instantaneous current voltage relation of i_{K_2} usually shows a marked inwardly directed rectification and a considerable negative slope[2].

The results reported here (Fig. 4) demonstrate that neither methoxamine nor methoxamine plus adrenaline alter the absolute magnitude or the rectifier properties of i_{K_2}.

Our results support the idea that i_{K_2} is governed by β-receptors[6-9] and they exclude the possibility that α-receptors influence i_{K_2}. Thus, it is not surprising that drugs selectively stimulating α-receptors do not have a positive chronotropic action on cardiac muscle.

Spontaneous repetitive hyperpolarisations from cells in the rat adenohypophysis

SPONTANEOUS, repetitive potential changes in the form of action potentials have been observed in only a few types of highly specialised cells such as cardiac pacemaker cells, various smooth muscle cells and certain nerve cells. Some endocrine cells, however, can exhibit repetitive depolarisations with similarities to action potentials; for example, the beta cells of the pancreas[1], cells in the adrenal cortex[2] and cells of a clonal line of an anterior pituitary tumour[3]. We report here that some cells in the adenohypophysis of ovariectomised rats are electrically excitable as well as exhibiting spontaneous, repetitive hyperpolarisations.

The rats were ovariectomised 3–5 weeks before the experiments, to induce hypertrophy of the pituitary gonadotropic cells and produce a more uniform population of cells from which more stable recordings of membrane potentials could be obtained. One hemilobe of the anterior pituitary gland was mounted in a Perspex chamber and superfused with Krebs–Henseleit bicarbonate solution at 37 °C, in a manner similar to that described before[1]. Membrane potentials were recorded from superficial cells by means of glass microelectrodes filled with 5 M potassium acetate with a resistance of 70–150 MΩ. A bridge circuit was used for intracellular recording and injection of current.

It was difficult to obtain stable measurements of membrane potentials from the cells of the adenohypophysis, but in 13
Fig. 1 Intracellular recording from an anterior pituitary cell exhibiting spontaneous, repetitive hyperpolarisation. The cell, which had a resting membrane potential of -42 mV, exhibited spontaneous hyperpolarisations at a frequency of 25 min^{-1} for 4 min before the record in a was obtained. The left part shows the effect of a depolarising current, and the right shows the effect of a hyperpolarising current. b Indicates that the current passed through the microelectrode. This and all subsequent records, were made by means of a pen recorder and the pituitary was obtained from a rat ovariectomised 4 weeks before study.

successful experiments recording from 127 cells the mean value was -49.3 ± 2.6 mV (s.e. of mean), which is more negative than previous *in vivo* measurements[4] (-21 mV) and *in vitro* measurements on pituitary tumour cells[3] (-41 mV). In eight experiments in which the input resistance—taken as a measure of the cell membrane resistance—was determined by passing small depolarising currents with the bridge balanced before and after penetration, the mean value was 118 MΩ (range 5–330 MΩ). This value is slightly larger than that found in a previous study[4] of *in vivo* rat pituitary (42 MΩ) but less than the value observed[3] with a clonal line of pituitary tumour cells (340–700 MΩ).

One population of cells with a mean resting potential of -37.1 ± 1.7 mV ($n=12$) and a mean resistance of 111 ± 31 MΩ ($n=7$) was peculiar in exhibiting spontaneous, repetitive hyperpolarisations. The mean frequency was 37.5 min^{-1} (range 2–65) and the mean amplitude was 16.0 mV (range 8–26). The record shown in Fig. 1 demonstrates the phenomenon and shows that the frequency of the hyperpolarisations increased when a small depolarising current was passed through the membrane. When the cell was hyperpolarised by a current passed in the opposite direction, the amplitude of the hyperpolarisations was reduced substantially, whereas the frequency

Fig. 2 Intracellular recordings demonstrating the excitability of the hyperpolarising cells. a, Ability of a depolarising current (indicated on the lower trace) and b, ability of termination of a hyperpolarising current (indicated on the lower trace) to evoke repetitive hyperpolarisations from an otherwise inactive cell.
did not change appreciably. Although most of these cells continued their repetitive hyperpolarisations for as long as 24 min, in a few cases the hyperpolarisations ceased even though the resting potential remained unchanged. In these cells, as well as in some cells which did not exhibit spontaneous hyperpolarisations, it was possible to initiate repetitive hyperpolarisations either by passing a depolarising current or by termination of a hyperpolarising current (Fig. 2).

A few cells transiently increased their resting potentials to values as negative as -75 mV. When this happened, the magnitude of the repetitive hyperpolarisations decreased successively and they were abolished at membrane potentials ranging from -55 to -70 mV. When the resting potential exceeded the value at which the hyperpolarisations were abolished, the polarity of the potential changes was reversed. Subsequently the resting potential of these cells returned to the original value (close to -40 mV) whereby the hyperpolarising behaviour was restored. It was also possible to change the spontaneous, repetitive hyperpolarisations to depolarisations by passing a hyperpolarising current sufficient to increase the resting potential beyond the 'reversal potential' (Fig. 3a).

Since hyperpolarisation of cell membranes is frequently a result of an increased permeability to potassium ions, we
Fig. 3 Intracellular recordings from spontaneously, repetitively hyperpolarising cells. a, Changes in amplitude and polarity of the spontaneous, repetitive potential changes caused by variations in the resting membrane potential. The left part shows the effect of a spontaneous increase in the resting potential, and the right shows the effect of hyperpolarisation caused by a current (indicated on the lower trace) passed through the microelectrode. b, Effect of increasing the extracellular potassium ion concentration on amplitude and frequency of repetitive hyperpolarisations. From the time indicated by the arrow, a modified Krebs–Henseleit bicarbonate solution with a potassium ion concentration of 47 mM (10 times normal, sodium ion concentration reduced correspondingly) was passed through the superfusion chamber at a rate of 0.78 chamber volume per min.

studied the effect of raising the potassium ion concentration of the superfusion fluid tenfold (to 47 mM). Figure 3b demonstrates the resulting decrease in the amplitude of the hyperpolarisations; the hyperpolarisations were subsequently abolished (not shown). The resting membrane potential was reduced by the high potassium ion concentrations, and this reduction was associated with an increase in the frequency of the hyperpolarisations. All the effects of the high extracellular potassium ion concentration were reversible.

Although it is not known from which cells in the adenohypophysis the spontaneous, repetitive hyperpolarisations originate, it is possible that the potentials have been recorded from

the gonadotropic cells, which exhibit selective hypertrophy after ovariectomy. Our inability to record spontaneous, repetitive hyperpolarisations from the adenohypophyses of normal rats gives some support to this view.

In cells able to hyperpolarise in response to stimulation, for example, nerve cells stimulated by inhibitory transmitter substances[5], salivary gland acinar cells stimulated by autonomic nerves[6] and certain photoreceptor cells stimulated by light[7], a common underlying mechanism is a stimulation-induced increase of the conductance of the cell membranes to potassium ions. In contrast, the cells in the adenohypophysis can produce repetitive hyperpolarisations in the absence of any obvious discontinuous, repetitive stimulus. The effect of increasing the extracellular potassium ion concentration indicates that a cyclic, transient increase in the conductance of the cell membrane to this ion may be involved in the hyperpolarisations. On the other hand, the value of the reversal potential is compatible with additional conductance changes to other ions such as sodium and calcium. The latter possibility is interesting because uptake of extracellular calcium ions is an important step in many secretory processes[8].

Although our results suggest that the hyperpolarising cells have pacemaker-like properties, there is an alternative possibility. If the hyperpolarising cells were connected to spontaneously discharging nerve cells through both an inhibitory chemical and an electrical synapse, the observed behaviour could be explained by postulating that the electrical synapse showed rectification. Neurones connected by both electrical and chemical synapses have been demonstrated[9,10]; neurones innervating adenohypophyseal secretory cells, however, have not been demonstrated.

The excitability of the hyperpolarising cells (Figs 1 and 2) show certain similarities to the excitability found in depolarising pituitary tumour cells by Kidokoro[3]. The cells described here however, are unique both in hyperpolarising in response to direct electrical stimulation and in showing repetitive hyperpolarisations.

Increase in microviscosity with ageing in protoplast plasmalemma of rose petals

IT is now widely accepted that most physiological functions of biological membranes are related to the dynamic characteristics of transport, enzyme and receptor sites. Since the rotational and translational mobility[1], as well as the degree of exposure of membrane proteins[2], are largely determined by the fluidity of the lipid layer, membrane microviscosity may be important in regulating various physiological activities, as in lymphocytes[3-5] and erythrocytes[6]. To our knowledge, changes in fluidity of plant plasmalemma, the outer surface of the protoplast[7], have not yet been reported. We report here a gradual increase in microviscosity of protoplast plasmalemma from petals of ageing rose flowers.

Rose (*Rosa* hyb.) flowers cv. Golden Wave (Syn. Dr. Verhage) were allowed to develop and age on the plant and were picked at different stages of development—from a tight bud to a fully opened flower with first signs of wilt and colour fading. The four outer petals of the flowers were macerated enzymatically in 0.6 M mannitol (Merck) containing 0.5% cellulysin (Calbiochem) and 0.25% driselase (Kyowa Hakko Koggo Co.) by incubation for 18 h at 20 °C in the dark. As a reporter molecule, we used 1,6-diphenyl-1,3,5-hexatriene (DPH), the most efficient probe available for monitoring fluidity properties of lipid regions by fluorescence polarisation[2-4,8]. For labelling, isolated protoplasts were incubated for 1 h at 37 °C with 10^{-6} M dispersion of DPH in 0.6 M mannitol. The labelled protoplasts were then washed and resuspended in 0.6 M mannitol to a concentration of 5×10^6–8×10^6 ml^{-1}. A fluorescence microscopic view of a DPH-labelled protoplast is of a glowing periphery, indicating that the fluorescence signal is generated predominantly from the hydrocarbon layer of the protoplast plasmalemma.

Fluorescence polarisation and intensity in the labelled protoplast suspension were recorded, and the corresponding microviscosity evaluated by a method described previously[2,3,8]. Figure 1 shows the change in microviscosity of the protoplast plasmalemma with stage of development of the petals. As shown, the membrane microviscosity ($\bar{\eta}$) gradually increases with the flower development. The rate of increase in $\bar{\eta}$ is markedly enhanced during the 4-d period between stage C (partially opened flower) and stage E (wilting flower), when the microviscosity is approximately doubled. The effect of temperature on the plasmalemma microviscosity was also determined in each stage in the temperature range of 4–30 °C. For all membranes, the change of log $\bar{\eta}$ with the reciprocal of the absolute temperature ($1/T$) followed a straight line with an apparent flow activation energy (ΔE) of 3.4 ± 0.2 kcalorie mol^{-1}. As an

example, Fig. 2 shows plots of log $\bar{\eta}$ against $1/T$ obtained for plasmalemma from stages D and E (see Fig. 1).

The data now available for plant membranes are still few and insufficient. The conclusions that can be drawn from this study are therefore bound to facts which were established for mammalian membranes. The unusually low and invariable value of $\Delta E = 3.4$ kcalorie mol^{-1} (in mammalian membranes $\Delta E = 6.5$–8.5 kcalorie mol^{-1}, (see ref. 2)) indicates that the lipid domains of the plasmalemma are highly ordered, even though they maintain a relatively high fluidity. In addition, it suggests that the membrane function and organisation are only slightly affected by temperature changes, which may be a special feature of plant membranes. A combination of these properties has no parallel in mammalian membranes, and indicates that the lipid composition, organisation and dynamics of plant and mammalian membranes are basically different. Nevertheless, the increase of plasmalemma microviscosity with the age of the flower could result primarily from one (or a combination) of the following changes: (1) an increase in the molar ratio of sterols to phospholipids; (2) a decrease in the degree of unsaturation of the fatty acid chains; (3) an increase in the relative amount of membrane proteins. Changes of the first[9] and the second[10] kind have been observed in aged plant tissues. The increase in microviscosity caused by such changes may decrease the turnover of membrane enzymes and hormone receptors and thus attenuate some metabolic processes which will eventually lead to the death of the flower[11–13].

Spin label study of erythrocyte membrane fluidity in myotonic and Duchenne muscular dystrophy and congenital myotonia

INTACT erythrocyte membranes from patients with myotonic muscular dystrophy (MMD) have been shown by spin labelling (review of method in ref. 1) to have greater membrane surface fluidity than normal[2,3]. We have now evaluated the specificity of this phenomenon. We used erythrocytes from patients with MMD, and also from patients with Duchenne muscular dystrophy (DMD), as a model of dystrophy with no myotonia, and from patients with congenital myotonia (CM) as a model of myotonia without dystrophy.

MMD has been considered a defect of muscle surface membrane based on the persistence of repetitive membrane depolarisation after nerve block or neuromuscular blockade[4]. A similar locus has been postulated for the membrane defect is congenital myotonia[4]. Our previous biochemical and biophysical studies have suggested that in MMD, there are membrane abnormalities in erythrocytes as well as muscle membranes[2,3,5–8]. Membrane protein phosphorylation is lower than normal[5,6] and the stoichiometry of the sodium pump is unusual[7]. An abnormally large number of stomatocytes was noted by scanning electron microscopy in MMD as well as several other inherited muscle diseases, including CM and DMD[8]. Studies with stearic acid methyl ester spin labels have demonstrated that MMD erythrocyte membranes are more fluid near the membrane surface than are those of normal controls[2,3]. The data now reported indicate similarly high erythrocyte fluidity near the membrane surface in CM, whereas erythrocytes from DMD and other non-myotonic muscular dystrophic patients have normal membrane fluidity as assessed using 5-NMS (see below). These results suggest a correlation of increased membrane fluidity with the presence of myotonia.

The principal spin label we used was 2-(3-carboxypropyl)-2-tridecyl-4,4-dimethyl-3-oxazolindinyloxyl methyl ester (5-nitroxide methyl stearate) (5-NMS) (Syva Associates). The erythrocytes were obtained from fresh heparinised blood from patients and from age and sex-matched controls. In experiments with MMD cells, data previously obtained[3] from seven normal and nine myotonic patients were recalculated as described below. Samples from twelve normal and ten DMD patients and nine normal and nine CM patients, respectively, were used. In each of the three separate sets of experiments, intact erythrocytes were prepared by centrifuging blood at 1,570g for 10 min at 4 °C and washing the cells four times with 5 mM sodium phosphate–150 mM NaCl buffer, pH 8.0 (PBS). The buffy coat was removed carefully and the cells were resuspended in isotonic PBS at a haematocrit of 45–50%.

Intact MMD cells were labelled overnight at 37 °C and intact CM and DMD cells were incubated with 5-NMS at room temperature for 10–30 min. In each respective set of experiments, control and disease state membranes were treated identically. The ratio of spin label to lipid molecules were kept at approximately 1:50 to avoid spin exchange effects[9]. Magnetic resonance measurements were performed as before[3] on both a Varian V-4502-15 and a Ventron-Magnion MVR-9X electron spin resonance (ESR) spectrometer, with a quartz aqueous sample cell.

The spin label we used is thought to orient in the erythrocyte membrane with the polar head group near the lipid head group and the alkyl chain parallel on the average to the lipid alkyl

chains. Rapid anisotropic rotation takes place about the long axis of the spin label whose nitroxide group probes an environment near the membrane surface. A typical spectrum of 5-NMS in erythrocyte membranes is shown in Fig. 1, in which the experimental T-tensor parameters are indicated. The order parameter, S, is a measure of the fluidity of the local environment in which the paramagnetic centre of the spin label is found while a_N, the nitrogen isotropic hyperfine coupling constant, is a probe of local polarity. Regardless of whether the random walk model of Jost *et al.*[10] or the model of Mason *et al.*[11] (which involves an inverse relationship between the rate of rotation of the symmetry axis and the apparent values of both S and a_N) is used to explain spectra like those of Fig. 1, the interpretation of S as a measure of local fluidity is valid. The polarity correction factor used by Hubbell and McConnell[12] with the crystal T-tensor values of "doxyl"-propane reported by Jost *et al.*[10], were used in the calculation of S.
Fig. 1 Typical spectrum of 5-NMS in normal erythrocytes. The tensor parameters are indicated.

The mean S values for controls and each disease state performed in the three separate sets of experiments were compared by a two-way analysis of variance[13] (Table 1). This two-tailed method of statistical analysis minimises possible fluctuations from day to day between separate experimental values which can often occur with biological samples.

P is the significance of the difference of the mean values of $S_{control}$ and $S_{disease\ state}$ (or $(a_N)_{control}$ and $(a_N)_{disease\ state}$) in each set of experiments calculated using a two-way analysis of variance. The null hypothesis was that MMD, DMD and CM membranes are, respectively, not different from the corresponding controls. The difference of $S_{control}$ and S_{MMD} or S_{CM} is significantly greater than zero, indicating more fluid environments in erythrocytes from these myotonic conditions. In contrast, there is no mean difference of $S_{control}$ and S_{DMD} and, accordingly, no difference in surface membrane fluidity. In this latter case the data actually tended to show DMD erythrocytes to be more rigid than controls but statistical significance of this observation could not be demonstrated.

The difference between the mean values of the control parameters in the MMD experiments compared with those in the CM and DMD experiments probably reflects the different

Table 1 Comparison of the order parameter S for 5-NMS in normal and MMD, DMD or CM intact erythrocytes

N, normal. S is calculated by

$$\frac{T_{\parallel}' - T_{\perp}' \quad a_{xl}}{T_{\parallel} - T_{\perp} \quad a'}$$

where the primed values are obtained experimentally (Fig. 1) and $a' = (T'_{\parallel} + 2T'_{\perp})/3$. The unprimed crystal values are obtained from the results of Jost *et al.*[10] on doxyl-propane. The data for MMD were from ref. 3, recalculated by a two-way analysis of variance. Data from three separate sets of experiments are presented. P was calculated by a two-way analysis of variance using a two-tailed test with a null hypothesis that the respective means are equal.

methods of labelling used. Intact erythrocytes held for several hours at 37 °C rapidly lose intracellular ATP with a consequent decrease in cell deformability[14]. This latter property may reflect an increased membrane rigidity which in turn would demonstrate an increased order parameter. Intact erythrocytes labelled overnight at 37 °C show an increased S-value when compared with cells from the same donor labelled for 15 min at room temperature (D.A.B., unpublished). The a_N value of 5-NMS in control cells is also increased in the MMD experiments compared with those of the other two sets of experiments (Table 2), suggesting that the spin probe is experiencing a different environment in the former case. The important aspect of these data in that within each separate set of experiments, normal and disease state membranes were treated in the same manner.

Our previous results[3] recalculated by the two-way analysis of variance show MMD erythrocyte membranes to have greater than normal surface fluidity as assessed by 5-NMS and less than normal local polarity, as measured by 16-NMS, relative to those of normal controls. The study reported here demonstrates that membrane fluidity is greater than normal in CM but not different from controls in DMD, hyperkalaemic periodic paralysis (without para-myotonia) or oculopharyngeal muscular dystrophy. There are no highly significant polarity changes as measured by a_N in the various experiments (Table 2).

We also found greater than normal membrane fluidity in MMD and CM erythrocytes when we used the corresponding acid spin label (5-NS) in identical procedures. The same differences of fluidity in erythrocyte ghost preparations[6] as in intact cells were also observed.

Table 2 Comparison of a_N for 5-NMS in normal and MMD, DMD or CM intact erythrocytes

The data for MMD were from ref. 3, recalculated by a two-way analysis of variance.
P was calculated as in Table 1.

Increased membrane fluidity has been demonstrated in both MMD and CM erythrocyte membranes by means of ESR spectroscopy. Although this method detects a fluidity increase in both cases, the specific biochemical alterations responsible for the change in these diseases may be quite different. Lower than normal phosphorylation of component a has been demonstrated in MMD erythrocyte ghosts, while CM ghosts do not have such biochemical alteration[16]. Physiological data also support different mechanisms of myotonia. Muscle membranes from CM demonstrate greater than normal resistance and less than normal chloride conductance, while these characteristics are not apparently affected in MMD[4]. It is interesting that the two myotonic diseases MMD and CM involve abnormal membrane fluidity of erythrocytes whereas DMD and the other two non-myotonic dystrophies apparently do not.

Membrane fluidity is a function of many variables, including the nature of membrane lipids (type of phospholipid, fatty acid chain length and degree of unsaturation, head group and cholesterol content), temperature, water content, presence of ions (especially divalent cations), and the total of protein-lipid interactions[16,17]. Activity of membrane-associated transport enzymes in bacterial[18] and animal[19,20] systems can be altered by affecting membrane fluidity. Increased membrane fluidity in MMD and CM may affect the expression of a transport or enzyme system resulting in the clinical sign of myotonia in muscle. Although the specific mechanism responsible for these

phenomena is unknown, our spin label measurements suggest a correlation of increased erythrocyte membrane fluidity with the presence of myotonia.

Vitamin D-stimulated intestinal calcium absorption may not involve calcium-binding protein directly

One of the earliest responses of chick intestine to cholecalciferol (vitamin D_3) is the appearance of a soluble calcium-binding protein (CaBP) for which current evidence indicates a role in the intestinal absorption of calcium[1,2]. CaBP, which has never been detected in the intestine of cholecalciferol-deficient chickens, is synthesised *de novo* in response to cholecalciferol, apparently by the induction of the transcription of a specific mRNA for CaBP (ref. 3). In the chick CaBP biosynthesis is initiated after a lag of about 7 h after physiological doses of the vitamin. A correlation between the appearance of CaBP and the first detectable increase in calcium absorption in response to cholecalciferol was observed when CaBP was measured using immunological procedures[4,5] but not using the less sensitive Chelex assay[6]. Consequently it has been generally accepted that CaBP plays a major role in chicks in cholecalciferol-stimulated calcium transport, but by a mechanism which has still to be described. These changes in intestinal

CaBP levels and in calcium absorption are brought about by 1,25-dihydroxycholecalciferol (1,25-$(OH)_2D_3$), the hormonal metabolite of D_3. We report here the sequence and time scale of changes in calcium absorption and CaBP levels in the intestine in response to 1,25-$(OH)_2D_3$. By comparison with events observed after cholecalciferol administration, the changes in response to the hormone turn out to be much more rapid and to have different rates of decay, with calcium transport being stimulated before CaBP can be detected immunologically.

Using immunoelectrophoresis[7] we have measured the amount of CaBP in the intestinal mucosa of rachitic chicks at various intervals after injecting 1,25-$(OH)_2D_3$ intracardially. CaBP was first detected 5 h after dosing (7 h earlier than after an equivalent dose of cholecalciferol) and by 16 h had increased to a level of 35 µg per g wet weight mucosa. Maximal quantities (42 µg g^{-1}) were obtained by 48 h, the levels declining to about 50% of the maximum by 72 h (Table 1); the protein could not be detected again by 96 h.

The ability of rachitic chicks to transport calcium across the intestine after receiving 1,25-$(OH)_2D_3$ was measured *in vitro* using everted intestinal sacs[8]. Sacs prepared from birds killed

Table 1 Calcium-binding protein levels in intestinal mucosa of rachitic chicks treated with 1,25-$(OH)_2D_3$

*, CaBP was detectable but in amounts too low for measurement. Groups of six rachitic chicks received intracardial injections of 125 ng 1,25$(OH)_2D_3$ in 0.1 ml 10% EtOH and 90% propylene glycol, and were killed at the times shown. CaBP was measured in the pooled duodenal cytosols by immunoelectrophoresis[7] using pure CaBP as standard.

2 h after dosing, transported calcium at a rate significantly higher than that of the controls, the maximum rate being reached by sacs obtained from birds 8 h after dosing (Fig. 1). By 21 h the ability of the sacs to transport calcium had declined to a rate slower than that occurring at 2 h. Thus by 4 h, 1,25-$(OH)_2D_3$-stimulated calcium transport was occurring at more than 50% of the maximum measured rate, whereas CaBP could not be detected. By 21 h, when calcium transport had declined markedly, the intestinal CaBP level was approaching its maximum. This lack of correlation between calcium transport and the quantity of CaBP induced by a single injection of 1,25-$(OH)_2D_3$, at both short and longer time intervals, suggested that the production of CaBP might be an event secondary to the hormonal stimulation of calcium transport. We therefore re-examined the phenomena using more sensitive methods for the detection of CaBP.

In the chick, cholecalciferol-stimulated CaBP appears to the greatest extent in the duodenum[9]. We therefore tested the ability of duodenal polysomes prepared from rachitic and 1,25-$(OH)_2D_3$-dosed chicks to synthesise CaBP in an *in vitro* cell-free system[11]. Incorporation of ^3H-leucine into completed polypeptide chains and into immunoprecipitable CaBP was determined. The specificity of the antiserum used to precipitate the tritiated CaBP was confirmed by analysing the dissociated immunoprecipitates on polyacrylamide gels. Typically, more than 80% of the total radioactivity recovered from the gel slices was localised in the CaBP peak. To measure CaBP synthesis, radioactivity in the CaBP area of the gels was related to the total TCA-precipitable incorporation into completed polypeptide chains.

Table 2 Effect of 1,25-(OH)₂D₃ on the synthesis of CaBP by polysomes *in vitro*

*Same birds were used for both polysome preparation and calcium transport measurements. At each other time, birds were taken from the same batch as those used for calcium transport.

Groups of four rachitic chicks received 125 ng 1,25-(OH)₂D₃ intracardially and were killed at the indicated times. Duodenal polysomes were prepared[10] and incubated for 40 min at 37 °C in triplicate 330-µl aliquots. The incubation medium contained 1 mM ATP, 0.1 mM GTP, 10 mM creatine phosphate, 40 µg ml⁻¹ creatine kinase, 50 µM of each amino acid except leucine, 5 µCi ml⁻¹ ³H-leucine, 0.5 mg ml⁻¹ polysomal RNA, 0.4 ml ml⁻¹ gel-filtered rat liver cell sap, 1 mM dithiothreitol, 4 mM MgCl₂, 100 mM KCl and 20 mM Tris-Cl pH 7.5. Duplicate 20 µl aliquots of the pooled triplicate postribosomal supernatants were removed for measurement of TCA-precipitable radioactivity in released protein. The remainder was immunoprecipitated with anti-CaBP as described previously[3]. The immunoprecipitate was dissolved by heating for 20 s at 90 °C in 100 µl SDS-Tris-dithiothreitol solution[12] and electrophoresed on SDS-acrylamide gels, which were then cut into 1-mm slices and processed for radioactive counting[3]. ³H radioactivity (d.p.m.) in the CaBP area of the gels is expressed as a percentage of the total TCA-precipitable incorporation into released proteins (corrected up to the maximum value obtained, that is, 1.4 × 10⁶ d.p.m. ml⁻¹) at each interval.

As shown in Table 2, CaBP mRNA activity was maximal 13 h after a single hormone injection, by which time CaBP represented 3–4% of the total protein-synthesising capacity of the polysomes (assuming a constant rate of translation). Polysomes from birds killed 1 h after receiving 1,25-(OH)₂D₃ were unable to synthesise CaBP. At this time, however, intestinal sacs prepared from the same birds could transport calcium at a low level (Fig. 1). Sacs prepared from birds killed 2 h after dosing, transported calcium at 27% of the maximum rate, but polysomes from these birds could only synthesise minute amounts of CaBP equivalent to 0.04% of the total proteins completed *in vitro*. Therefore, although translation
Fig. 1 Stimulation of *in vitro* calcium transport in chick intestine in response to 1,25-(OH)₂D₃. Rachitic chicks (other than controls) were dosed intracardially with 125 ng 1,25-(OH)₂D₃ and killed at the times shown. Sacs were constructed from 3.0 cm of ileum distal to the yolk sac remnant and filled with 0.3 ml medium. Incubation was carried out at 37 °C for 90 min with shaking in 25-ml Erlenmeyer flasks containing 3.0 ml of the same medium in 95% O₂/5% CO₂. A low sodium medium was used to reduce water transport[11]; this contained 198 mM mannitol, 25 mM KCl, 1.2 mM NaH₂PO₄, 25 mM NaHCO₃, 1.2 mM MgSO₄, 20 mM glucose, 0.5 mM CaCl₂ and ⁴⁵Ca at a concentration of 40,000 c.p.m. ml⁻¹. Aliquots (100 µl) were removed from the serosal and mucosal solutions after incubation for measurement of radioactivity. Each point is the mean of a group of 7–10 chicks. Vertical bars indicate ± s.e.m. A low level of calcium transport seemed to be taking place after 1 h (P < 0.3) but significant transport did not occur until 2 h (P < 0.001).

of CaBP mRNA *in vivo* had commenced by 2 h after dosing, CaBP production represented only 1.0% of the maximum activity attained.

Thus, at all times at which calcium transport could be observed at a significantly higher rate in dosed chicks than in rachitic birds, we detected nascent CaBP on the polysomes. We have also detected very low amounts (0.01% of total protein synthesis) of soluble (that is, completed, released from polysomes and presumably functional) ³H-CaBP synthesised *in vitro* by intestinal slices obtained from birds killed 2 h after
Fig. 2 Time course of events occurring in the rachitic chick intestine after a single intracardial injection of 125 ng 1,25-(OH)₂D₃. ■, Calcium transport *in vitro*; ●, CaBP mRNA activity; ▲, CaBP level in intestinal cytosol.

dosing (data not shown), confirming the presence of minute amounts of CaBP in the intestine at this stage. None was detectable at 1 h. From the composite data presented in Fig. 2, however, by 3 h after dosing, when calcium transport is proceeding at 50% of its maximum rate, CaBP biosynthesis is occurring at only 2.5% of its maximum rate, and in general the response curve of the latter lies about 2.5 h after the former.

It is also apparent from Table 2 and Fig. 2 that after 13 h the ability of the polysomes to synthesise CaBP declined rapidly, being completely absent by 48 h. This suggests that the half life of CaBP mRNA is not more than 4 h; high levels of CaBP observed in intestinal supernatants between 16 and 48 h and its disappearance between 48 and 96 h therefore indicate that the accumulated CaBP is stable within the 3–4-d life of the cell, rather than that a steady-state situation of continued synthesis and breakdown exists. In addition, the continued presence of CaBP in mucosal cells at times when calcium transport is no longer detectable indicates that other vitamin D-dependent factors are required.

There have been reports of a correlation between changes in calcium absorption and in CaBP levels which occur in chicks in response to cholecalciferol[4-6]. Before the present study, it seemed that a correlation could be demonstrated providing that the CaBP levels were measured by immunological procedures. Furthermore, the available information from two laboratories[13,14] on the effect of 1,25-(OH)₂D₃ on chick intestine seemed to support this view, but in both studies the times at which comparisons were made were too late to detect calcium transport in the absence of CaBP. In our studies, in which changes in calcium absorption and CaBP after 1,25-(OH)₂D₃ were compared at hourly intervals, calcium transport occurred while CaBP was absent or present in very small amounts. Thus, it is unlikely that CaBP is required for the initial calcium transport occurring in response to 1,25-(OH)₂D₃, although the possibility remains that only a small proportion (0.01–1.0%) of the CaBP ultimately synthesised in response to the hormone actively promotes calcium transport. If such a small proportion of CaBP is active in calcium absorption there are implications for the mechanism by which the protein is effective. That finding would imply a catalytic role for CaBP rather than its functioning in a stoichiometric relationship with the calcium being transported[15]. In addition, the intracellular distribution of this small quantity may be different from the distribution of the total CaBP eventually produced by the cell[16]. It seems

unlikely, however, that the bulk (> 99%) of the CaBP in the mucosal cell is inactive. We therefore conclude that there is not an obligatory requirement for CaBP in all calcium transport.

Whether such a conclusion is applicable to mammalian intestine awaits further investigation. The present position is that the absence of CaBP in the intestine of rachitic animals of some species as claimed by some investigators[17,18] is open to doubt[19,20], although there is general acceptance that its synthesis is increased by the vitamin[17-21]. Resolution of this problem requires specific antisera to an intestinal CaBP preparation from a mammalian species in which vitamin D deficiency is readily produced.

Factors involved in initiation of haemoglobin synthesis can be phosphorylated *in vitro*

RABBIT reticulocytes, after incubation in a nutritional medium with radioactive inorganic phosphate, contain a significant amount of covalently bound phosphate. Approximately 65% of this phosphate is attached to ribosome-associated proteins which are released into the 0.5 M KCl wash fraction from ribosomes; the remainder is bound to ribosomal protein[1]. The high salt wash fraction contains various proteins required for the initiation and maintenance of protein synthesis. To analyse the effects of phosphorylation on the regulation of protein synthesis, purified initiation factors from rabbit reticulocytes have been examined for phosphate-acceptor activity through the use of cyclic AMP-regulated and cyclic nucleotide-independent protein kinases. Here we describe the phosphorylation of two factors previously shown to be involved in the initiation of haemoglobin synthesis. Both IF-MP, the Met-tRNA$_f$ binding factor, and IF-M2A, a ribosome-dependent GTPase activity, are modified by a cyclic nucleotide-independent protein kinase isolated from rabbit reticulocytes. Initiation factors IF-M1 (ref. 2), IF-M2B$_\alpha$ (ref. 3), IF-M2B$_\beta$ (ref. 3), IF-M3 (ref. 4) and IF-M4 (ref. 5) are not phosphorylated by this enzyme.

The cyclic nucleotide-independent protein kinase activities in the post-ribosomal supernatant fraction were isolated by chromatography on DEAE–cellulose (Fig. 1). Enzyme activity was monitored by incorporation of radioactive
Fig. 1 Isolation of cyclic nucleotide-independent protein kinase activity from rabbit reticulocytes by chromatography on DEAE–cellulose. The post-ribosomal supernatant fraction was prepared and chromatographed on DEAE–cellulose as previously described[6] except that 600 mg of protein was added, and elution was with a 600-ml linear KCl gradient ranging from 0 to 0.5 M KCl. Protein kinase activity was assayed using γ-^{32}P-ATP (●) and γ-^{32}P-GTP (○) as previously described[6]. The activity referred to as III$_C$ in the text comprises fractions 54–79. Fractions 54–62, 67–72 and 74–79 were pooled individually, dialysed against 20 mM Tris-HCl, pH 7.5, 6 mM mercaptoethanol and 1 mM EDTA and stored at 4 °C.

phosphate from γ-^{32}P-ATP and γ-^{32}P-GTP into casein. The major protein kinase activity (III$_C$) elutes between 0.24 and 0.34 M KCl and is observed to contain several chromatographically different species. The protein kinase activity was pooled into three fractions as indicated in the legend to Fig. 1, and the enzyme activity in each of these fractions was analysed as a function of increasing concentrations of monovalent and divalent cations and for substrate specificity. No differences were observed among the three fractions (data not shown). The DEAE–cellulose column fractions were also analysed for cyclic AMP-regulated protein kinase activity using histone IIA (Sigma) as substrate in the presence of 1.4×10^{-6} M cyclic AMP. The regions where these two protein kinases eluted are indicated by arrows in Fig. 1. Further chromatography of the cyclic AMP-regulated protein kinases resolved these enzymes from cyclic nucleotide-independent activities[6].

Highly purified initiation factors from rabbit reticulocytes were incubated with the cyclic AMP-regulated and cyclic nucleotide-independent protein kinase activities using either radioactive ATP or GTP as the phosphate donor. Phosphate-acceptor activity of the initiation factors was demonstrated by electrophoresis of the incubation mixture on polyacrylamide gels containing sodium dodecyl sulphate (SDS) followed by autoradiography. IF-MP was phosphorylated as shown in Fig. 2. This initiation factor has been

Table 1 Effect of cyclic AMP and cyclic GMP on phosphorylation of IF-MP and IF-M2A

	IF-MP		IF-M2A	
	ATP	GTP	ATP	GTP
	^{32}P incorporated (pmol µg^{-1})			
Protein kinase (67–72)	2.7	1.9	11.6	8.0
+ cyclic AMP	2.4	1.9	13.6	9.7
+ cyclic GMP	2.5	2.1	12.1	10.7

The stained initiation factors obtained after polyacrylamide gel electrophoresis as described in Figs 2 and 3 were excised, dried and counted in a Beckman liquid scintillation counter with a toluene cocktail mixture.

purified to homogeneity[7], and has been shown to form a ternary complex with Met-tRNA$_f$ and GTP[8]. It is composed of three subunits which migrate with molecular weights of 57,000, 53,000 and 38,000 in polyacrylamide gels containing SDS[9]. The subunit with a molecular weight of 53,000 is phosphorylated by the cyclic nucleotide-independent protein kinase (III$_C$) using either ATP or GTP. With the reaction conditions used, 0.45 mol of phosphate were incorporated per mol of IF-MP, assuming a molecular weight of 180,000 (ref. 7). IF-MP is not modified by cyclic AMP-regulated protein kinases II or III$_H$.
Fig. 2 Phosphorylation of IF–MP. IF-MP (1.4 μg) was phosphorylated in 0.045 ml of reaction mixture containing 50 mM Tris-HCl, pH 7.0; 10 mM MgCl$_2$, 0.14 mM γ-^{32}P-ATP (0.2 Ci mmol^{-1}) or γ-^{32}P-GTP (0.12 Ci mmol^{-1}); 1.4 × 10^{-6} M cyclic nucleotide (where indicated), and protein kinase. The reaction contained 7 enzyme units (EU) of III$_U$ (fractions 74–79), 25 EU of II, (further purified by chromatography on phosphocellulose[6]), or 20 EU of III$_H$ (purified further by chromatography on carboxymethyl Sephadex). A unit of protein kinase activity has been defined previously[6]. Incubation was for 20 min at 30 °C and terminated by the addition of SDS in sample buffer. Slab gel electrophoresis was performed using the gel system of Laemmli[21] as described by Ames[22] with the following modifications: the ratio of acrylamide to *bis*-acrylamide was 22.2 : 0.6; the electrode buffer contained twice the concentration of Tris-HCl and glycine; and the resolving gel and the stacking gel acrylamide concentrations were 10% and 5% respectively. Electrophoresis was at room temperature for 0.5 h at 100 V followed by 3.5 h at 150 V. The gels were stained in Coomassie brilliant blue, destained and autoradiographed for 3–4 h against Kodak No-Screen medical X-ray film. Samples (*a–d*) contained ATP and III$_C$. *a*, IF-MP omitted; *b*, no additions; *c*, plus cyclic AMP; *d*, plus cyclic GMP. Samples (*e–h*) contained GTP and III$_C$. *e*, IF-MP omitted; *f*, no additions; *g*, plus cyclic AMP; *h*, plus cyclic GMP. *i*, Contained ATP, cyclic AMP, and II; *j*, contained ATP, cyclic AMP and III$_H$.

Fig. 3 Phosphorylation of IF-M2A. The procedures were described for Fig. 2 except that 1.5 μg of homogeneous IF-M2A was reacted with 3 EU of protein kinase III$_C$ (fractions 67–72) in a final volume of 0.025 ml for 10 min. The stacking gel contained 2.5% acrylamide and the voltage for the first 0.5 h of the run was 75 V. For identification see Fig. 2.

IF-M2A which catalyses a ribosome-dependent GTPase activity was also modified by the cyclic nucleotide-independent protein kinase activity that phosphorylates IF-MP (Fig. 3). This initiation factor has been observed to stimulate protein synthesis using either a natural or artificial template and has been purified to homogeneity[10]. As observed in the autoradiogram, either ATP or GTP can be the phosphate donor. With optimal incubation conditions, approximately two phosphoryl moieties can be incorporated per polypeptide of molecular weight 125,000, and both serine and threonine residues are modified (data not shown). IF-M2A is not modified by either of the cyclic AMP-regulated protein kinases.

The effects of cyclic AMP and cyclic GMP on the phosphorylation of both initiation factors are shown qualitatively by autoradiography in Figs 2 and 3. To quantify the effects of these nucleotides on the phosphorylation of the initiation factors, the radioactive proteins were excised from the gel, dried and counted in a liquid scintillation counter. Table 1 shows that cyclic AMP and

cyclic GMP neither stimulate nor inhibit the phosphorylation of IF-MP and IF-M2A at 10^{-6} M. In the conditions of the reaction, ATP is slightly more effective as a phosphate donor than GTP. Both the ATP and GTP were examined by thin-layer chromatography on PEI cellulose and found to be chromatographically pure with regard to contaminating radioactive nucleotides. Thus, both nucleotide triphosphates are authentic phosphate donor compounds in the reaction. Both initiation factors are modified by the three chromatographically different fractions of protein kinase which comprise III$_C$. These three fractions show little or no difference in the extent to which they phosphorylate the initiation factors.

Our results provide the first evidence of a cyclic nucleotide-independent phosphorylation of initiation factors which are involved in the complex process of protein synthesis. The phosphorylation of a single 40S ribosomal protein in rabbit reticulocytes has been shown to be controlled by cyclic AMP[1,11]. Phosphorylation of the same protein in rat liver increases considerably when the liver is forced to regenerate[12] or in conditions of experimental diabetes[13].

Evidence suggests that the role of haemin in the regulation of protein synthesis is mediated by phosphorylation. In the absence of added haemin, inhibition of protein synthesis in a reticulocyte lysate occurs at chain initiation with a concomitant decrease in binding of Met-tRNA$_f$ to 40S ribosomal subunits[14,15]. This inhibition is potentiated by the addition of ATP[16,17]. Inhibition produced by haemin deprivation is prevented in the reticulocyte lysate by high concentrations of GTP[16,17], cyclic AMP[17,18] and various purines[18], and by the addition of IF-MP[19]. A protein kinase activity has been identified with the purified inhibitor fraction[20]. Since the protein kinase activity described here makes use of both ATP and GTP as substrate, it is questionable whether this enzyme has the requisite properties for the translational inhibitor. But we have recently isolated another cyclic nucleotide-independent protein kinase activity which initially copurifies with cyclic AMP-regulated protein kinase III$_H$. This cyclic nucleotide-independent activity modifies the small subunit of IF-MP and may be the haem-controlled repressor (S.M.T., J.A.T., B.S. and W.C.M., in preparation).

Thus there are at least two possible mechanisms for the control of translation by phosphorylation—cyclic AMP-regulated modification of the 40S ribosomal subunit and cyclic nucleotide-independent phosphorylation of the initiation factors. We are analysing the differential phosphorylation of the two factors and the 40S ribosomal subunit in order to understand the molecular basis for the control of protein synthesis by phosphorylation.

Evidence for involvement of nuclear envelope nucleoside triphosphatase in nucleocytoplasmic translocation of ribonucleoprotein

A NUCLEOSIDE triphosphatase activity showing broad substrate specificity has been found in nuclear envelope isolated from rat and pig liver, *Tetrahymena* macronucleus, and cultured SV-3T3 fibroblasts using the method of Harris and Milne[1], and has been extensively characterised in this laboratory. There is evidence that in purified nuclear envelopes there is only one enzyme which catalyses nucleoside triphosphate hydrolysis: the activities observed with different substrates and metal ions are not additive, and they show a single pH optimum, the value of which varies with the source of the envelopes[2]. This enzyme seems to be localised in the nuclear pore complexes[3]. Several reports[4–13] have indicated that ATP markedly stimulates the release of mRNA from isolated nuclei, but no evidence has been presented to suggest that this stimulation necessarily requires hydrolysis of the ATP. In this paper, however, we present evidence that the nucleoside triphosphatase is an essential component of the mechanism of nucleocytoplasmic translocation of ribonucleoprotein.

SV-3T3 cells were grown in Dulbecco's modified Eagle's medium (Flow Laboratories) and labelled for 6 h with 10 μCi $^{14}C_6$-orotic acid (61 mCi mmol^{-1}, Amersham). The cells were homogenised in 10 mM Tris-HCl, pH 7.4, containing 1 mM MgCl$_2$, and centrifuged through 2.2 M sucrose in the same Tris–MgCl$_2$ buffer at 100,000g for 1 h at 0 °C. The pellet of nuclei was substantially free of 5′ nucleotidase
Fig. 1 Time course of RNA release from isolated nuclei. All experiments were carried out at 35 °C in the following medium[13]: 50 mM Tris-HCl, pH 7.6, 25 mM KCl, 2.5 mM MgCl$_2$, 0.3 mM MnCl$_2$, 0.5 mM CaCl$_2$, 5.0 mM NaCl, 2.5 mM K$_2$HPO$_4$, 5.0 mM spermidine and 2.0 mM dithioerythrytol. ○, Control; ●, release on addition of 2.0 mM ATP; ×, release on addition of 2.0 mM EDTA; △, release on addition of 2.0 mM adenylyl-β,γ-methylene diphosphonate (AMP.PCP); □, difference between ATP-stimulated and control values. After 30 min incubation, $74 \pm 4\%$ of the counts released in the control and $90 \pm 5\%$ of the additional counts released in the presence of ATP were precipitable with 5% TCA. There was no significant difference between the release in the presence of EDTA and that in the presence of AMP.PCP; indicating that, contrary to the finding of Raskas[7], the effect of AMP.PCP is solely attributable to its chelating action. The effect of ATP, however, is clearly not wholly attributable to chelation.

(EC 3.1.3.5), Na/K-stimulated Mg-ATPase (EC 3.6.1.4) and succinate dehydrogenase (EC 1.3.99.1), and no organelle contamination was visible under phase contrast (B.McC., P.S.A. and J. F. Lamb, unpublished). Digestion of the nuclei in 0.1 M NaOH and counting in a Packard Tri-Carb scintillation spectrophotometer using NE 250 scintillant (NEM) showed ^{14}C incorporation of $5,000 \pm 1,000$ c.p.m. per 10^6 nuclei. In the presence of 50 μg ml^{-1} proflavine, orotic

Table 1 Specificity of the nucleoside triphosphatase and of nucleoside-triphosphate-stimulated RNA release from isolated nuclei for various divalent cation–nucleoside triphosphate complexes

Substrate	a	b
Mg.ATP^{2-}	16.7 ± 1.1	438 ± 21
Mg.GTP^{2-}	18.0 ± 1.1	450 ± 22
Mg.UTP^{-}	7.9 ± 0.5	219 ± 15
Mg.CTP^{2-}	7.2 ± 0.5	153 ± 13
Ca.ATP^{2-}	13.4 ± 1.1	350 ± 19

a, Nucleoside triphosphatase activity (μmol inorganic phosphate released per h per mg protein). *b*, Stimulated RNA release (c.p.m. per h per 10^6 nuclei)—that is, the difference between counts released in the presence and in the absence of the nucleoside triphosphate. For the release experiments, nuclei were incubated at 35 °C in 0.88 M sucrose containing either 5 mM MgCl$_2$, CaCl$_2$, MnCl$_2$, ZnCl$_2$ or BeCl$_2$, and the 5% TCA precipitate of the supernatant was counted as described in the text[4]. The results in column *b* are in good agreement with those of Ishikawa *et al.*[4].
Fig. 2 Eadie plots comparing dependence of rates of nucleoside triphosphatase reaction (○) and ATP-stimulated RNA release from nuclei (●) on ATP concentration. For the left-hand ordinate (S/v RNA release), the v term has been taken as the difference in label released (c.p.m. per h per 10^6 nuclei) in the presence and absence of ATP at each concentration. For the right-hand ordinate (S/v enzyme), the v term is the nucleoside triphosphatase activity (μmol phosphate released per h per mg envelope protein). Enzyme assays were carried out as described in the text, the free Mg^{2+} concentration being maintained at 0.2 mM throughout[2,18]. RNA release experiments were carried out essentially as described in Fig. 1; but to avoid spurious results due to the chelating action of ATP, EDTA was added to make the total ATP+EDTA concentration 1.0 mM throughout. K_m values obtained are 0.26 ± 0.05 mM for the nucleoside triphosphatase, and 0.30 ± 0.09 mM for the ATP-stimulated RNA release. The agreement between the behaviour of the two processes is again close.

acid incorporation was reduced to 850 c.p.m. per 10^6 nuclei, indicating that most of the label was taken up into the nuclear RNA[14].

The media described by Ishikawa *et al.*[4] and by McNamara *et al.*[13], which maintain the nuclei in a stable and essentially disaggregated state, were used in the RNA release experiments; the yeast RNA, ATP-generating system and cytoplasmic protein[13] were omitted. Volumes (0.75 ml) of a suspension containing approximately 5×10^6 nuclei ml^{-1}, with and without ATP (routinely 2.0 mM) and other reagents, were incubated at 35 °C for various times. The suspension was centrifuged at $3,000g$ for 5 min to remove nuclei, and 0.4-ml aliquots of the supernatant counted as before.

The nucleoside triphosphatase activity proved resistant to all attempts at solubilisation. Enzyme assays were therefore carried out by incubating whole nuclear envelopes in 25 mM triethanolamine–HCl buffer, pH 7.7, with ATP and $MgCl_2$

Table 2 Effects of various inhibitors on the nuclear envelope nucleoside triphosphatase and on ATP-stimulated RNA release from isolated nuclei

Inhibitor	a	b
Ouabain 2.0 mM	100 ± 8	100 ± 9
Gramicidin 50 μg ml^{-1}	100 ± 6	100 ± 3
Cycloheximide 50 μg mL^{-1}	100 ± 4	100 ± 7
Oligomycin 5 μg ml^{-1}	85 ± 5	82 ± 8
50 μg ml^{-1}	60 ± 10	52 ± 6
Quercetin 5 μg ml^{-1}	50 ± 6	35 ± 5
15 μg ml^{-1}	Trace	Trace
AMP.PCP 2.0 mM	100 ± 7	100 ± 6
ATP γ S 1.0 mM	50 ± 10	38 ± 6
2.0 mM	16 ± 8	Trace

a, Nucleoside triphosphatase activity; b, rate of RNA release. All values are expressed as percentage of control ±1 s.e.m. ATP γ S, Adenosine-5'-O-(3)-thiotriphosphate. ATP analogues were obtained from Boehringer; other inhibitors from Sigma.

at 35 °C for 30 min, and determining inorganic phosphate release[15]. In experiments in which the effects of inhibitors were investigated, the nuclei or envelopes were preincubated with the inhibitor for 5 min, and solvent blanks were used as controls.

Substrate specificity, kinetic behaviour and inhibition properties of the ATP-stimulated RNA release were investigated and compared with the corresponding properties of the nucleoside triphosphatase, to establish whether there was a causal connection between the two processes. The effect of ATP on RNA release from the nuclei is shown in Fig. 1: 25–30% of the label released in the absence of exogenous ATP is attributable to low molecular weight (TCA-soluble) material; the remainder presumably represents leakage of RNA from the nuclei, although the possibility that traces of endogenous ATP may contribute to the background cannot be ruled out. Preliminary isotachophoretic measurements indicate not more than 20 nmol ATP per 10^6 freshly prepared nuclei.

Table 1 shows that replacement of other nucleoside triphosphates for ATP and of other divalent cations for Mg^{2+} still resulted in stimulation of RNA release from the nuclei. There is a striking correlation between this stimulated release and the rate of hydrolysis catalysed by the nucleoside triphosphatase for all divalent cation–nucleoside triphosphate complexes investigated. The nuclear envelope contains an active glucose-6-phosphatase (EC 3.1.3.9) (ref. 3), but replacement of ATP by 2.0 mM glucose-6-phosphate was not attended by significant stimulation of the RNA release.

Table 2 compares the effects of inhibitors on the nucleoside triphosphatase and on the ATP-stimulated release of RNA. Again, the correlation is striking, particularly so because the inhibitor concentrations for half-maximal inhibition were similar for both processes. The dependence of the rate of ATP-stimulated RNA release on ATP concentration approximated to Michaelis–Menten kinetics, with a K_m' value $(2.8\times10^{-4}$ M) close to that for the nucleoside triphosphatase (Fig. 2). For all properties investigated, therefore, there was a close correspondence between the behaviour of the two processes, indicating a likely causal connection.

There is strong evidence that the RNA released as a ribonucleoprotein complex into the supernatant in the conditions described in this paper is predominantly mRNA. Although the possibility of some contamination with heterogeneous nuclear RNA cannot be ruled out, normal nuclear restriction of RNA has been clearly demonstrated using the medium described by McNamara *et al.*[16] and Ishikawa *et al.* note that the RNA released in the conditions they use in the presence of ATP is largely incorporated into polysomes[17]. If these *in vitro* conditions, which have been used in the present investigation, can be accepted as a reasonable facsimile of conditions *in vivo*, then the results we have described here strongly suggest that the nuclear envelope nucleoside triphosphatase constitutes an essential part of the mechanism of nucleocytoplasmic ribonucleoprotein translocation. Detailed kinetic studies of the enzyme have been carried out in this laboratory[18], with a view to illuminating the molecular mechanism of this translocation process.

Unexpected occurrence of an aminoacylated nucleoside in mammalian tRNATyr

MANY tRNAs contain a hypermodified nucleoside at the 3' side of their anticodons[1]. The modifications at this position are essential for tRNA function in ribosome binding and amino acid transfer[2-4], and cause inability to base pair according to the Watson–Crick scheme[5]. A striking correlation between the codon response of the tRNA and the nature of this hypermodified nucleoside has been observed: all known sequences of tRNAs (*Escherichia coli*), with codons beginning with uracil, contain N^6-(Δ^2-isopentenyl)-2-methylthio-adenosine at the 3' side of the anticodon[6-8], whereas tRNAs with codons starting with adenine, contain an aminoacylated nucleoside, such as N-[N-(9-β-D-ribofuranosyl-purin-6-yl)carbamoyl] threonine (t^6A) or the methyl derivative (mt^6A) at this position[9,10].

The same distribution of these isopentenylated and aminoacylated nucleosides has also been observed in yeast[11-13] and mammals[14,15]. This striking regularity led to the widely accepted postulate that N^6-(Δ^2-isopentenyl-adenosine) (i^6A) or the methylthiolated derivative might have a specific role in the recognition of codons starting with uridine[1], whereas t^6A is thought to prevent pairing between uridine in the third position of the anticodon and guanine in the first position of the codon[16].

The Tyr-tRNAs read the UAX-codons and contain in *E. coli*[17,18], *Torulopsis utilis*[19], and yeast[11] i^6A next to the anticodon, as expected. Tyr-tRNA from rat liver, however, chromatographs very differently from the i^6A-containing species on partition chromatography columns[20], and elutes at about the same position as tRNA$_3^{Ser}$ which contains the hydrophilic nucleoside mt^6A (ref. 15). This chromatographic behaviour

of tRNA^{Tyr} (rat liver) indicates the presence of a polar nucleoside in the anticodon loop of this molecule. As mentioned, t^6A was thought to be present exclusively in tRNAs coding for AXX codons, so we did not expect it in tRNA^{Tyr}, which codes for UAX. Here we report the unexpected occurrence of t^6A in tRNA^{Tyr} from rat liver.

tRNA^{Tyr} was purified from crude rat liver tRNA (ref. 21) using two different fractionation procedures. The first involved fractionation on BD–cellulose column chromatography[22] at pH 4.5. The tRNA^{Tyr}-enriched fractions were then separated on a DEAE–Sephadex A 50 column[23] at pH 7.3, further purified on a BD–cellulose column in 7 M urea[24] at pH 4.5, and finally separated on a reversed phase column (system 5)[25]. The second purification method consisted of fractionation on a BD–cellulose column in 7 M urea at pH 4.5, then the tRNA^{Tyr}-enriched fractions were phenoxyacylated[26] and rechromatographed using the same chromatography system. The latter method takes advantage of the fact that a modified uridine in tRNA^{Tyr} reacts specifically with the phenoxyacylating reagent leading to a more lipophilic elution position of the derivatised tRNA, so that tRNA^{Tyr} can be separated rapidly from non-derivatised material[27]. From the elution profile of other tRNAs one can conclude that the structures of hypermodified nucleosides in the anticodon loop are not affected by this method.

After enzymatic hydrolysis to nucleosides, pure fractions of tRNA^{Tyr} (rat liver) were analysed by two-dimensional thin-layer chromatography on cellulose-coated aluminium foils, as described previously[28]. The nucleosides were identified by their characteristic chromatographic behaviour and by their ultraviolet absorption spectra at pH 1, 6 and 12, as well as by their characteristic fluorescence and phosphorescence at 77 K (ref. 29). The two-dimensional chromatogram of a hydrolysate of rat liver tRNA^{Tyr} is shown in Fig. 1. With the exception of the chemically modified uridine derivative in case of the phenoxyacylated tRNA, identical patterns were obtained by analysis of fractions from the two different purification methods. The following nucleosides were found: adenosine, 13-15; cytidine, 19-20; guanosine, 20-22; uridine, 10-11; pseudouridine, 3-4; ribothymidine, 1; dihydrouridine, 3-4; 1-methyladenosine, 1; 5-methylcytidine, 1; 1-methylguanosine, 1; N^2-methylguanosine, 1; N^2,N^2-dimethylguanosine, 1; 7-methylguanosine, 1; and an unknown uridine derivative (U*) which reacts with the phenoxyacylating reagent. Neither i^6A, nor one of its derivatives, was found in the hydrolysate. Instead, one residue of the nucleoside t^6A, which is found exclusively at the 3' position adjacent to the anticodon, was detected. Since t^6A was thought to be present only in tRNAs coding for AXX codons and therefore should not occur in the tyrosine-specific tRNA, we proved the identity of t^6A by the following extensive criteria. (1) The ultraviolet absorption spectra of the compound at different pH showed the same characteristics as those of the synthetic t^6A (Fig. 2). (2) After alkaline hydrolysis of t^6A from tRNA^{Tyr} with KOH (0.3 M, 16 h, 37 °C)
Fig. 1 A two-dimensional thin-layer chromatogram of the digest of tRNA^{Tyr}. 2–3 A_{260} units of the desalted tRNA^{Tyr} were degradated enzymatically overnight at 37 °C by 25 μg pancreatic RNase (Boehringer GmbH, Mannheim), 30 μg snake venom phosphodiesterase (Worthington) and 25 μg alkaline phosphatase (Worthington, Code BAPF) in a siliconised test tube containing 0.02 M ammonium formate (pH 7.6) and 5×10^{-4} M MgCl$_2$ in 0.2 ml (ref. 28). The digest was subsequently treated for 2 h at 37 °C with 5 μg ribonuclease T$_1$ (Calbiochem) and then applied on a cellulose-coated aluminium foil, as described previously[28]. The solvent systems used (see Table 1) were solvent C in the first dimension and solvent D in the second. The arrow indicates the established position of isopentenyladenosine which is absent in this hydrolysate.

and removal of the potassium with perchloric acid, the ultraviolet absorption spectra of the hydrolysate was identical to that of adenosine. In addition, the degradation product also showed mobility identical to adenosine on three different thin-layer chromatographic systems. (3) Automatic amino acid analysis after degradation of the compound in $Ba(OH)_2$ (0.1 M, 20 min in a boiling water bath and 16 h at 37 °C, followed by removal of Ba^{2+} with sulphuric acid) yielded equal amounts of threonine and serine. Control experiments using synthetic t⁶A established that in these hydrolysis, considerable amounts of threonine were degraded to serine. (4) The chromatographic properties of t⁶A from tRNA^{Tyr} in four different solvent systems were identical to those of synthetic t⁶A and different from either its glycine analogue g⁶A or mt⁶A (Table 1). (5) Chromatography on DEAE-cellulose at pH 8–8.8 showed that the compound had a negative charge like t⁶A and differed therefore from another aminoacylated derivative which had been isolated from tRNA$_2$^{Met} (*E. coli*)[1] and which would be uncharged at this pH.

These findings clearly prove the presence of the aminoacylated nucleoside t⁶A in tRNA^{Tyr} (rat liver). Analysis of

Table 1 Chromatographic mobilities of aminoacylated nucleosides compared with t⁶A from tRNA^{Tyr} (rat liver) in four different solvent systems

Nucleoside	R_F values ($\times$ 100) in solvent			
	A	B	C	D
t⁶A from tRNA^{Tyr} (rat liver)	49	53	10	30
t⁶A (synthetic)	49	53	10	30
mt⁶A	58	59	13	27
g⁶A	38	48	5	10
adenosine	54	74	42	11

The following solvent systems (cited in ref. 28) were used: A, *n*-propanol–concentrated ammonium hydroxide–water (90:45:15, by volume); B, isobutyric acid–ammonium hydroxide (0.5 M)–EDTA (0.1 M) (100:60:1.6, by volume); C, 1-butanol–isobutyric acid–water–ammonium hydroxide (25%) (150:75:50:5, by volume) D, saturated ammonium sulphate–sodium acetate (0.1 M) (pH 6)–isopropanol (79:19:2, by volume).

tRNA^{Tyr} from the silk worm (*Bombyx mori*), showed that in tRNA^{Tyr} from this organism, i⁶A is also replaced by t⁶A, indicating that t⁶A in tRNA^{Tyr} seems to be a common feature of higher organisms—thus contrasting strongly the situation in *E. coli*[6–8] and yeast[11–12].

It is particularly interesting that the nature of the base adjacent to the anticodon of tRNAs coding for UXX codons is very different in *E. coli* and in mammals. In *E. coli* this position is always occupied by N^6-(Δ^2-isopentenyl)-2-methylthio-adenosine, whereas in higher organisms there were detected (in addition to isopentenyl-adenosine) wybutosine (Y) in tRNA^{Phe} (yeast)[30], 1-methyl-guanosine in tRNA$_3$^{Leu} (yeast)[31], adenosine in tRNA^{Trp} (yeast)[32] and derivatives of wybutosine in tRNA^{Phe} of wheat germ[33] and mammals[34–37]. This may indicate that the problem of recognition of these tRNAs by the ribosome might be solved differently in prokaryotes and higher organisms.

We thank Drs G. B. Chheda and M. P. Schweizer for synthetic aminoacylated nucleosides (t⁶A, mt⁶A, g⁶A), Dr J.-P. Garel for the sample of pure tRNA^{Tyr} from *Bombyx mori*, and Drs J. Gordon, G. A. Howard and J. P. Jost for critical reading of the manuscript.

to laser excitation of rhodopsin. Highly pure rhodopsin solutions in 0.067 M phosphate buffer (2% Ammonyx LO) were prepared as described previously[14–16].

Characteristic oscillograms, showing the main transient decay patterns after pulsed (530 nm, 40 ns) Nd laser excitation of rhodopsin solutions at 22 °C, are shown in Fig. 1. Oscillograms (*a–d* and *f*) were recorded using a pulse energy of ~20 mJ which is sufficiently high to reach saturation (absorbance changes independent of the pulse intensity), reflecting the attainment of a photostationary equilibrium between the primarily excited rhodopsin and photoproducts formed during the pulse (for example, PLR)[12]. Oscillogram *e* was recorded with a reduced pulse intensity, as indicated by the drop in the transient absorbance relative to, for example, *f*. Figure 1*a* and *b* shows that the initial changes at the end of the pulse are followed by decay and growing-in processes, exhibiting a half life of ~100 ns. These fast events are followed by much slower changes in the μs range (Fig. 1*c* and *d*). The corresponding difference spectra, recorded 50 ns, 700 ns and 1 ms from the origin of the pulse (Fig. 2), are proportional to the differences $D_T^\lambda - D_R^\lambda$, where D_R^λ is the drop in the absorbance of rhodopsin due to photobleaching and D_T^λ is the (time-dependent) absorbance of photoproducts present after the pulse. The dotted curves in the range where experimental points are not available were estimated as described below.

Primary processes in photochemistry of rhodopsin at room temperature

MOST of the information concerning the primary photochemical events in vision has been derived from low temperature work[1–5]. Recently, pulsed laser excitation methods with nanosecond[6–8] or picosecond[9] time resolution have been applied, in an attempt at clarifying the primary act at physiological temperatures. These studies showed that prelumirhodopsin PLR; or bathorhodopsin), which is the primary photoproduct at 77 K, is also formed at room temperature, with a rise time of less than 6×10^{-12} s (ref. 9) and a half life of ~10^{-7} s (refs 6–9). The problem remained, however, as to whether other primary transients, in addition to PLR, are formed at room temperature[8]. It is also important to establish if PLR is the unique precursor of the visual sequence at physiological temperatures, ruling out direct routes to subsequent intermediates—for example, lumirhodopsin (LR)—circumventing PLR. The present pulsed Nd laser study has attempted to clarify the above points, essentially testing the applicability of the low temperature photochemical picture (refs 10 and 11, and T.R., B. Honig, M.O. and T. Ebrey, unpublished) in physiological conditions.

The Nd laser photolysis system has been described previously[12]. Photolysis of the rhodopsin samples by the monitoring light was minimised by using short (10^{-2} s) exposures (obtained with a synchronised camera shutter) and appropriate combinations of Corning glass filters. Nanosecond measurements (with the monitoring source used in an intense pulsed mode) were not carried out in the 480–520-nm range, where no such filter combinations could be found, to reduce bleaching by the monitoring light (to less than ~5%) without lowering its intensity (*I*) below the minimum required[13]. The range between 520 and 550 nm was also avoided because of interference from light scattered by the laser. The above limitations on *I* impose serious restrictions on the signal-to-noise ratio (S/N) of the present nanosecond laser experiments (Fig. 1*a* and *b*, S/N = 5–10). A more intense monitoring pulse, however, significantly improving the accuracy of the measurements, pumps the system to an undefined mixture of rhodopsin and its bleaching products, preventing a quantitative analysis of the net effects due

Fig. 1 Characteristic oscillograms in the Nd laser photolysis of rhodopsin at room temperature. The initial absorbance of the solutions at 495 nm ranged from 0.5 to 1.0. Experiments *a*, *b*, *c* and *f* were carried out using a 20-mJ pulse, whereas *e* was carried out using a reduced intensity (oscillator only, without amplification). Load resistors used: 50Ω (*a*, *b* and *d*); 10 KΩ (*c*) and 100 KΩ (*e* and *f*). 100% (*c–f*) and 2% (*f*) denote the percentage of transmitted monitoring light. Upper traces in *c–f* were recorded in the absence of the monitoring beam. Vertical sensitivity 20 mV (*a*, *b*, *d* and *e*, central trace); 10 mV (*c*); 200 mV (*e*, bottom and upper traces); 100 mV (*f*). The initial light to dark deflections (not shown) in *a* and *b* were 180 mV and 170 mV, respectively. The break in the lower traces in *c* and *e* is due to firing of the laser pulse. In all other cases the laser was fired almost simultaneously with the oscilloscope trigger. In oscillogram *f* the lower trace denotes the transmittance of a bleached rhodopsin solution. The two central traces were recorded in an unbleached solution, without (upper) and with (lower) the laser being fired. From this information it is possible to evaluate the absorbance of the solution before pulsing and the change induced by the laser pulse between 1 and 7 ms. This enables evaluation of percentage rhodopsin bleached, as described in the text.
Fig. 2 Transient absorbance changes after pulsed Nd laser excitation of rhodopsin at room temperature. Data were recorded 50 ns (*a*), 700 ns (*b*) and 1 ms (*c*) after firing the laser. In *a* and *b* the spectral resolution is of the order of 5 nm (above 350 nm) or 10 nm (below 350 nm).

Oscillograms *c* and *d* in Fig. 1 and curve *c* in Fig. 2 show that after ~ 0.3 ms, bleaching in the range of the 500-nm rhodopsin band is associated with an increase in absorbance at about 380 nm, characteristic of the spectrum of meta-rhodopsin II (MII)[2,17,18]. Similarly, the difference spectra *a* and *b* may be associated with the generation of PLR (λ_{max} at 77 K = 543 nm) and LR (λ_{max} = 490 nm). (In the present experiments we have not attempted to identify MI, the precursor of MII, the absorption spectrum of which is similar to that of LR.) A closer examination of Fig. 2 indicates, however, that the observed difference spectra cannot be rationalised only in terms of PLR, LR and MII. In all three cases the absorbance change in the 450–550-nm range is higher than that expected from the corresponding low temperature differences in extinction coefficients[1,17,18]: $\varepsilon_{M_{II}}^{\lambda} - \varepsilon_L^{\lambda}$, $\varepsilon_R^{\lambda} - \varepsilon_R^{\lambda}$ and $\varepsilon_{PLR}^{\lambda} - \varepsilon_R^{\lambda}$, indicating that apart from PLR an additional product (X) is present at the end of the pulse which is stable at least up to the stage of MII. A new band in the neighbourhood of 450 nm was also reported by Bensasson *et al.*[8] along with a peak at about 330 nm, not observed in the present work.

Information relevant to the identification of X was obtained by measuring its contribution, reflected by the absorbance drop at 480 nm (at the stage of MII) relative to that at 550 nm, as a function of the laser pulse intensity. Excitation below saturation (for example, Fig. 1*e*), when the amount of light absorption by PLR relative to rhodopsin is considerably reduced, leads to an increase in the above ratio ($D_{480}/D_{550} = 2.2 \pm 0.4$), compared with that ($0.9 \pm 0.3$) obtained using saturating excitation energies (for example, Fig. 2*c*). It seems therefore that X is a secondary product, formed during the pulse because of light absorption by PLR. Thus, in view of the photoequilibrium

$$\text{rhodopsin} \underset{h\nu}{\overset{h\nu}{\rightleftarrows}} \text{PLR} \underset{h\nu}{\overset{h\nu}{\rightleftarrows}} \text{Isorhodopsin (IR)}$$
$$(\lambda_{max} \text{ at } 77 \text{ K} \qquad (\lambda_{max} \text{ at } 77 \text{ K} \qquad (\lambda_{max} \text{ at } 77 \text{ K}$$
$$= 498 \text{ nm}) \qquad\qquad = 543 \text{ nm}) \qquad\qquad = 491 \text{ nm})$$
which is known to be established at 77 K (refs 3 and 19), it is strongly suggested that X should be identified with the 9-*cis* isomer, IR (λ_{max} at 25 °C = 485 nm)[11].

This suggestion may be more quantitatively tested by considering the change in absorbance after 1 ms at 550 nm (where $\varepsilon_{MII} \sim 0$)

$$\Delta D_{550} = C_{IR}\varepsilon_{IR}^{550} - C_{MII}\varepsilon_R^{550} - C_{IR}\varepsilon_R^{550}$$

Taking[11] $\varepsilon_{IR}^{550}/\varepsilon_R^{550} \sim 0.5$ and neglecting the contributions of

IR and rhodopsin at 380 mm (that is, approximating: $\Delta D_{380} \sim \varepsilon_{MII}^{380} C_{MII}$), we have

$$\Delta D_{550} = -\varepsilon_R^{550}(C_{IR}/2 + \Delta D_{380}/\varepsilon_{MII}^{380})$$

From the data of Fig. 2 (with $\varepsilon_{MII}^{380} = 4.0 \times 10^4$ M^{-1}cm^{-1} and $\varepsilon_R^{550} = 1.8 \times 10^4$ M^{-1}cm^{-1}) we obtain $C_{MII} = 4.5 \times 10^{-6}$ M and $C_{IR} = 6.6 \times 10^{-6}$ M. The concentration of bleached rhodopsin is $C_{IR} + C_{MII}$ and its contribution to the difference spectra in Fig. 2, $D_R^{\lambda} = \varepsilon_R^{\lambda}(C_{IR} + C_{MII})$ is shown in Fig. 3*a*. Addition of D_R^{λ} to each of the difference spectra in Fig. 2 yields curves *d*, *e* and *f* in Fig. 3, representing correspondingly D_T^{λ} (50 ns), D_T^{λ} (700 ns) and D_T^{λ} (1 ms). It can be seen that curve *f* can be represented by the superimposition of the known spectra[11,17,18] of MII (Fig. 3*c*) and IR (Fig. 3*b*), in keeping with the identification of X as IR. A similar procedure shows that curves *e* and *d* are obtainable by superimposing the contribution of IR and correspondingly (allowing for a 10–20-nm temperature shift and a $\sim 10\%$ change in extinction coefficients) those of LR and PLR in amounts equal to that of MII.
Fig. 3 *a*, Contribution of bleached rhopodsin (D_R^{λ}) to the difference spectra of Fig. 2; *b* and *c*, spectra of MII and of transient X (IR), respectively. *d–f*, Spectra of transients present after 50 ns (*d*), 700 ns (*e*), and 1 ms (*f*) evaluated from the corresponding traces in Fig. 2, as described in the text.

The above observations are consistent with PLR being the unique primary product in the photochemistry of rhodopsin at room temperature. It is also evident that it constitutes the precursor of the subsequent intermediates in the cycle (LR, MI, MII, and so on). Thus, the classical sequence of primary events as derived for rhodopsin on the basis of low temperature work[1-5] seems to be applicable at physiological temperatures, in agreement with a conformational (for example, *cis-trans*) change as the only primary step of the visual cycle (refs 10 and 11, and T.R. *et al.*, unpublished).

We thank Dr B. Honig, Dr A. Kropf and Dr R. Bensasson for discussions. T.R. is grateful for Professor T. Ebrey's invitation to join his laboratory in the State University of Illinois.

Structure of thymidylyl-3',5'-deoxyadenosine

THE triethylammonium salt of the dinucleoside phosphate, thymidylyl-3',5'-deoxyadenosine (TpdA) forms helical structures when aqueous solutions are allowed to evaporate[1]. There are some similarities between the X-ray diffraction patterns from TpdA and those from poly(dA-dT)–poly(dA-dT), and we originally thought that the structures might be similar[1]. But when the structure for poly(dA-dT)–poly(dA-dT) was proposed[2] it was apparent that the TpdA structure was not of the same kind. This, together with the fact that we had obtained more detailed X-ray diffraction patterns from better oriented TpdA specimens, led us to consider the different molecular model for TpdA which we describe here.

Figure 1a shows the diffraction pattern from a specimen of TpdA at ~ 60% relative humidity. The layer-line spacing corresponds to a periodicity of 26.4 Å and the equatorial Bragg reflections fit a hexagonal lattice with $a = 21.3$ Å. Discrete reflections are confined to the inner region of the equator—the remainder of the pattern shows continuous intensity along the layer lines. The strongest intensity is in the meridional region of the 7th layer line. The intensity on the 8th layer line is also very strong as well as the first maximum on the 1st layer line. The near meridional diffraction on layer lines 5–8 is similar to the diffraction in the same region in patterns from DNA, double-helical RNA and synthetic polynucleotides. It is mainly due to the bases and gives information about their tilt relative to the helix axis.

In the early photographs it was difficult to decide on which of the layer lines 5–8 the intensity was truly meridional and thus to decide the number of residues per turn of the helix. Better oriented specimens, tilted at 12° from perpendicular to the X-ray beam show that the intensity on the 5th and 8th layer lines is not meridional (Fig. 1b). But it is not possible to decide whether the truly meridional intensity occurs on the 6th or the 7th layer lines. Tilting a specimen at 24° from perpendicular to the X-ray beam to examine the meridional region of the 12th and 14th layer lines, it is again difficult to decide which of these two has truly meridional intensity (Fig. 1c). In fact the intensity on the 13th layer line seems to be more meridional, although this appearance could be a result of the intensity distribution on these layer lines, which is very dependent on the tilt of the bases.

Meridional intensity on the 7th and 14th layer lines would imply seven residues per turn of the helix, with a rise per residue of 3.77 Å and a rotation per residue of 51.4°. Meridional intensity on the 6th and 12th layer lines would imply six residues per turn, with corresponding translational and rotational values of 4.4 Å and 60°.

Our original idea that the TpdA structure might be similar to that of poly(dA-dT)–poly(dA-dT) would mean that the repeating unit of the structure was a pair of TpdA molecules related to each other by a twofold rotation axis perpendicular to the helix axis. The large tilt of the bases required to give the appropriate rise per residue in such a model is not however, consistent with the near-meridional intensity distribution in the diffraction pattern. We therefore considered alternative models, in which the repeating unit is one TpdA molecule and with a smaller tilt of the bases, as suggested by the near-meridional diffraction intensity. We assumed that within the dinucleoside phosphate, the two nucleosides are related by a right-handed screw, as in all other helical polynucleotide structures. We find that it is possible to construct a stereochemically acceptable model with seven TpdA molecules per turn of the helix, and which also gives a calculated Fourier transform which is in reasonably good agreement with the observed diffraction pattern (Fig. 2). A similar sixfold model does not give good agreement with observation.

The thymine of one TpdA molecule is hydrogen bonded to, and coplanar with, the adenine base of the next. This is only possible if one TpdA molecule is related to the next by a left-handed screw. The model is thus a left-handed helix, although within the dinucleoside phosphate unit, the nucleosides are related as in a right-handed helix. To use protein structure terminology, the secondary structure is right handed but the quaternary structure is left handed. Adenine and thymine are
Fig. 1 X-ray diffraction patterns from TpdA specimens at ~ 60% relative humidity. Diffraction photographs were taken on a North American Phillips microcamera, using a Hilger and Watts semimicrofocus X-ray generator. *a*, Specimen approximately perpendicular to X-ray beam; *b*, specimen tilted through 12°; *c*, specimen tilted through 24°.
Fig. 2 The cylindrically averaged molecular Fourier transform of the sevenfold TpdA model. The smooth curves indicate the calculated transform. Bragg reflection positions are indicated by vertical bars and the continuous intensity is represented by blocks. Modified atomic scattering factors[8], to allow for water in the structure, were used in the Fourier transform calculations.

Fig. 3 Projections of one TpdA molecule together with the adenine base of the next molecule above and the thymine base of the next molecule below. *a*, View perpendicular to the helix axis; *b*, view along the helix axis.

observed in some nucleotides[5-7]. A *gauche–gauche* conformation about the C(4′)–C(5′) bond consistently gave rise to an unacceptably short contact. Two views of the model are shown in Fig. 3, and a sketch of the model is shown in Fig. 4. There is a large degree of overlap between adenine bases but very little between

Fig. 4 Schematic representation of the model.

linked to each other by Hoogsteen[3] hydrogen bonds, and both adenine and thymine bases are in the anti conformation about the glycosyl bonds. The interaction between bases is thus similar to that between chains 2 and 3 in poly(dT)–poly(dA)–poly(dT) (ref. 4). The adenine–thymine bases are tilted about 9° from perpendicular to the helix axis so that the distance between adjacent adenine–thymine bases is less than the rise per residue. The glycosyl torsion angle O(1′)–C(1′)–N(9)–C(4) is 176° for the adenine base and the angle O(1′)–C(1′)–N(1)–C(2) is 220° for the thymine.

Both furanose rings have C3′ endo puckers, so the conformation is similar to that in A-DNA and double-helical RNA. Sugar rings with other kinds of pucker did not give such satisfactory models. The conformation of the C5′–O5′ bond about the C4′–C5′ bond in the link between the nucleosides is in the *gauche–trans* region. Although this is not the preferred conformation for this bond, similar conformations have been

the thymine bases. The structure is polar and the fact that the diffraction patterns have discrete reflections only in the inner region of the equator indicates that the 'up' and 'down' arrangement of helices in the specimens is random.

We thank Mr Ron Damaschka for computational assistance.

matters arising

Energy expenditure in children

IT was with interest that we read the paper by Griffiths and Payne[1], in which they presented interesting data and then discussed the possible relevance of environmental and genetic factors on the level and nature of the energy balance obtained with the two groups of children.

It is interesting to note that on expressing the mean expenditure and intake data for both groups as a ratio × 100, precisely the same figure ensues

$$\frac{\text{Energy expenditure}}{\text{Energy intake}} \times 100$$

Non-obese	Obese
$\frac{1,508}{1,433} \times 100 =$	$\frac{1,174}{1,115} \times 100 =$
105.23	105.29

Is it not possible therefore, that few overall metabolic differences exist between the 5-yr-old children of these two groups of parents, which by implication, suggests the predominance of environmental factors on these results?

It is surprising that the O group children were found to have lower daily energy intakes than their controls (N group). Therefore it would seem likely that parental pride during the nutritional survey may have had a marked influence.

We are also a little concerned that no comment was made about the data which showed that both groups of children were in negative energy balance, which for 5 yr olds would seem to be unlikely. From our experience SAMI measurements can be misleadingly high unless very precise and immobile electrical contacts are made, and thus background noise is eliminated.

1 Griffiths, M., and Payne, P. R., *Nature*, 260, 698–700 (1976).

GRIFFITHS AND PAYNE REPLY—In our view the most important findings in our study were the differences in total daily energy metabolism, and of resting metabolic rate between the two groups of children.

We agree that the measurements of daily expenditure by the SAMI technique are inherently less reliable than are those of food energy intake, and have offered them as supporting evidence. That is to say, unlike Miller and Otto[1], we regard the equal ratios of expenditure to intake as contributing positively to the evidence for different amounts of energy metabolised daily by the two groups.

Because the differences between the estimations of expenditure and intake (energy balance) are small in relation to the errors inherent in the two measurements, the energy balances do not statistically differ significantly from zero. We are not therefore inclined to attach any biological significance to the fact that they happen, on average, to be negative in both groups.

It is of course possible that one aspect of the behavioural differences between obese and normal people is that the former tend to 'cheat' when attempts are made to measure habitual intake, either their own or their children's. We can only repeat that: the O group children were not themselves measurably overweight so there was no obvious reason for the parents to take pride in suggesting that they eat sparingly, the degree of cooperation and the level of communication with the subjects about the objectives of the study were of necessity, very high, the admittedly less reliable estimates of expenditure closely parallel those of intakes, and show the same magnitude of difference between the groups.

Benzodiazepines and GABA

BASED on a few experiments on Deiters' neurones and cerebellar Purkinje cells, Steiner and Felix[1] concluded that benzodiazepines antagonise the inhibitory effect of GABA. To understand the mode of action of centrally acting agents, the evidence available from various pharmacological experiments must be considered and the manifold pitfalls inherent in the single-cell recording and microelectrophoretic techniques taken into account. The conclusion of Steiner and Felix[1] is in contrast to the well documented facts that benzodiazepines: (1) are the most potent antagonists of convulsions induced by picrotoxin and bicuculline[2-4] (generally accepted to block GABA receptors); (2) enhance presynaptic inhibition in the spinal cord and in the cuneate nucleus[2,5,6]; (3) enhance postsynaptic inhibition in the cuneate nucleus[6] and in the substantia nigra[2,7] and (4) are mutual antagonists of GABA receptor blockers at inhibitory synaptic processes believed to be mediated by GABA[5-7]. We think that the conclusion of Steiner and Felix[1] is based on the erroneous interpretation of experimental conditions that were inadequate for the specific problem.

In their experiments on vestibular neurones, they made the implicit assumption that the pulses applied to the cerebellar white substance (in their Fig. 1 either the time calibration is wrong or the rate of stimulation is not that indicated in the legend) released the same amount of GABA within the Deiters' nucleus before and after diazepam. This crucial premise is probably not correct for the following reasons. The stimulating electrode excites Purkinje cell axons directly and, in addition, evokes an unknown number of synaptically evoked discharges of Purkinje cells through the inevitable stimulation of cerebellar afferents. The number of the latter discharges depends on the balance between mono- and disynaptic excitation and the inhibitory influence on Purkinje cells. If diazepam, as we assume, enhances GABA-mediated synaptic inhibition also in the cerebellar cortex, it should reduce the number of Purkinje cell discharges evoked synaptically by the stimulus train, and thus, produce an apparent reduction of the inhibitory effect on Deiters' neurones, which was interpreted by Steiner and Felix[1] as an antagonism of the effect of GABA released within the vestibular nucleus. The apparent reduction by diazepam of the inhibitory effect of iontophoretically applied GABA may be explained in the same way. In the pre-drug period, the depression of Deiters' neurones is achieved by the fixed amount of

exogenous GABA which adds to the endogenous GABA that is released by the continuous activity of Purkinje cells. After diazepam, the spontaneous firing rate of Purkinje cells is markedly reduced[2,8]. This must result in disinhibition of Deiters' neurones and in the reduction of the total amount of GABA (exogenous plus endogenous) acting on them. The validity of our reasoning could easily be checked experimentally.

Any interpretation of the results of Steiner and Felix[1] on cerebellar Purkinje cells must remain highly speculative when taking into consideration that four of the five types of cerebellar cortical neurones are believed to be GABA-ergic and that the activity of the Purkinje cell is itself inhibited by GABA-ergic interneurones. In the experiments of Steiner and Felix[1] the benzodiazepines did not seem to depress the firing rate of Purkinje cell, whereas in our own experiments[2,8] several representatives of this class of compounds regularly and markedly reduced the spontaneous discharges and strongly antagonised the opposite effect of bicuculline. We should also like to emphasise that the experiments of Steiner and Felix[1] were performed on anaesthetised animals and a multitude of interactions between anaesthetics and benzodiazepines have been described.

In conclusion, it seems that the findings of Steiner and Felix[1] do not fail to support a facilitating effect of benzodiazepines on GABA-mediated transmission[2] but rather that they are easily explained by such a mode of action.

STEINER AND FELIX REPLY—The hypothesis advanced by Haefely *et al.*[1] that benzodiazepines facilitate GABA-responsive neurotransmission is based on the premise that GABA is the proven mediator of inhibition at presynaptic sites (this is still controversial, see refs 2 and 3) as well as on the demonstration

---

that the action of the presumptive GABA antagonists bicuculline and picrotoxin is reduced by this class of psychotropic drugs. Haefely *et al.*[1] are justified in pointing out that the mode of action of centrally acting drugs is bound to be complex and that more than one level of interaction ought to be considered. They fail to mention, however, that so far, there is no direct experimental support for their contention at any level of organisation tested: Neither their own work, nor that of others cited in support of their view, has directly tested GABA-mediated transmission, and thus all their experimental evidence is circumstantial. It was precisely for this reason that we chose to test their hypothesis at the level of identified Purkinje cells and Deiters' neurones[4]. At both these sites, there is incontrovertible evidence for GABA-mediated inhibition, the extent of which can readily be followed by standard electrophysiological techniques. In this anatomically and functionally well defined system, our results indicated that benzodiazepines inhibit GABA-responsive transmission[4]. We remain convinced that our technique is adequate to study the problem, and welcome this opportunity to answer questions raised by Haefely *et al.*[1] about our approach.

For the orthodromic activation of Deiters' neurones by stimulation of Purkinje cell axons, we deliberately chose supramaximal parameters (trains of three pulses of 250 μs duration at 500 -μs intervals and an intensity of 0.8 mA). Although we do not refute the view expressed[1] that this type of stimulations is likely to have repercussions on the cerebellar cortex as well as on nerve endings at the level of the Deiters' nucleus, we believe that, as in other biological systems, orthodromically stimulated transmitter release is a direct function of the stimulus applied (and therefore, in our case, a constant); we cannot accept their view that the amount of GABA

---

released in our experimental conditions is modified, in any important respect, by way of the soma of the Purkinje cells itself. With respect to the methodology used, we concede that in any study using microelectrophoresis, the quantity of exogenous neurotransmitter administered, albeit small in absolute terms, is likely to be in the pharmacological range. Changes in endogenous GABA release would therefore seem negligible compared with the amount of exogenous GABA administered. Haefely *et al.*[1] argue that a drop in endogenous GABA release by Purkinje cells (which, in keeping with their hypothesis, they ascribe to a facilitation of GABA-mediated inhibition by benzodiazepines at this site) could "easily" be distinguished from the fixed amount of exogenous GABA applied; in our view, this would require the direct monitoring of GABA release at Purkinje cell terminals on Deiters' neurones and could not reliably be deduced from the rate of cell firing alone (to our knowledge, such microtechniques are presently beyond our reach).

If Haefely *et al.* were correct in their assumption that benzodiazepines facilitate GABA-mediated inhibition at the Purkinje cell (and so reduce their GABA release), they would also have to concede a similar synergism at the GABA-responsive synapses impinging on the Deiters' neurones themselves; if their argument is taken to its logical conclusion, one would have to postulate that reduced GABA release at this site is counteracted, and possibly cancelled out, by an increase in its biological effect. This assumption, however is not borne out by our findings. Likewise, we consider the absence of benzodiazepine effects on the spontaneous rate of discharge of Purkinje cells as further evidence that our findings are not secondary to changes in the extent of excitation of the cerebellar cortex or the use of anaesthetised animals but are a reflection of drug interaction occurring at the site of study itself.

Our results, as well as those of Gähwiler[5], obtained in simple well defined systems, indicate a functional antagonism between GABA and benzodiazepines. They do not confirm the notion of a synergism inferred from indirect observations on more complex structures.

reviews

Marking time

Colin Renfrew

Radiocarbon: Calibration and Prehistory. Edited by Trevor Watkins. Pp. vi+147. (Edinburgh University: Edinburgh, January 1976.) £3.50.

THE tree-ring calibration of radiocarbon dating has had a number of striking archaeological consequences, bringing the historical and radiocarbon calendars for the ancient civilisations of the Old World into closer agreement and pushing the date of some cultures and monuments back much earlier than had been realised.

The intention of the symposium from which this volume springs was to "allow discussion of the subject of correction before a lay audience in terms which they could understand". Most of the contributions succeed well in this modest task. Richard Burleigh, for instance, advocates preliminary calibration for many purposes, while pointing out that for other purposes uncalibrated dates can often legitimately be compared. This view, however, is somewhat over-simplified by the editor: "it is too early to use the curves at present being bandied around as calibration curves for radiocarbon dates". Unfortunately the volume went to press before the publication by R. M. Clark of the most statistically sound and reliable of these (*Antiquity*, 49, 252–272, 1975).

The volume as a whole betrays a similar lack of balance. Alongside useful reviews of European dendrochronology by Fletcher and of the problem of irregularities ('kinks') by Ottaway and Ottaway, is a substantial disquisition by McKerrell (53 pages long, more than a third of the total) arguing the very special case that the existing calibration curves are reasonably sound except for the period between 2,500 BC and 1,500 BC (in calendar years).

This view is based on the assessment of radiocarbon and historical dates (the later derived from the Egyptian calendar) for Egypt, the Near East and the Aegean. Unfortunately the archaeology for the Agean is distinctly shaky (p61) and the treatment of the central European material (Veterov, Madarovce, and so on; p68) might have been more convincing at the hand of a professional archaeologist.

It is surprising that a scientific worker should propose, in the proceedings of a conference designed for laymen, a theory with major geophysical implications which might better first be offered to the critical scrutiny of his physicist colleagues. Moreover, when the theory that calibrated dates in general are sound (with the specific exception of a single millennium), has global implications, would it not be wise to consider the broader consequences outside of Europe?

What begins as a useful introductory handbook rapidly becomes a specialised and highly controversial critique of calibration, an argument *à thèse* rather than a clarification, on which the comments of competent radiocarbon specialists might have been invited. The editor could usefully have asked himself whether he wanted his book to be a searching professional critique of calibration, or a lucid, non-technical exposition. There is still a need for both. ☐

Colin Renfrew is Professor of Archaeology at the University of Southampton, UK.

Textbook of ichnology

The Study of Trace Fossils: A Synthesis of Principles, Problems and Procedures in Ichnology. Edited by Robert W. Frey. Pp. xiv+562. (Springer: Berlin and New York, 1975.) DM 141.70; $58.10.

MANY sedimentary rocks contain fossilised branching structures that a hundred years ago were mistakenly identified as seaweeds and called 'fucoids'. In the 1880's these were shown to be the tracks of animals, and in most parts of the world their study lapsed. But in Germany this was not at all the case. In 1925 Rudolf Richter founded a new school of *Akutuopaläontologie* in which the traces of animals played a vital part in the determination of environment. These early studies led to the establishment of a new and exciting discipline in which palaeontologists were able to postulate behavioural parameters. In this way 'palaeoethology' came to join 'palaeoecology' as a branch of 'geobiology'. In these studies the Germans remained far in advance of the rest of the world for over thirty years; and, indeed, it can still be said that they lead the field, with Professor Adolf Seilacher of Tübingen (who contributes a foreword to this book) as the acknowledged dean.

But at least nowadays the supremacy of our German colleagues in this field has been challenged. The discipline of palaeontology has much changed from the time when it was dominated by morphology and taxonomy. Its boundaries have extended, and in 1970 Crimes and Harper edited a remarkably successful symposium on trace fossils which reported the proceedings of an international symposium held in Liverpool. This was followed in 1971 by a field-guide to trace fossils produced by Louisiana State University. It has now been realised all over the world that ichnology plays a quite indispensable role in field studies aimed at interpreting past environments.

The present volume is the only textbook on the subject available in English. It captures well the excitement of a subject which to most of the world is still seen as new. The editor has kept his contributors well disciplined, so that in spite of the fact that it combines the work of no fewer than 28 authors, it retains an admirable cohesiveness as well as being comprehensive. For example, it includes chapters on both plant traces and vertebrate trails (both by William Sarjeant), and concludes with a fascinating section describing two new developments in ichnology— one on experimental methods (By Christopher Elders) and the other describing George Farrow's brilliant techniques for the study of the traces of living animals in present day sediments.

This book will certainly be regarded as an indispensable teaching aid in all future courses dealing with ichnology or palaeoethology, and the editor, Robert Frey, is to be congratulated on the clarity of exposition he has been able to command as well as the logic he

has imparted to the work as a whole. It is all the more to be regretted that the publishers, in spite of their reputation and their experience, have allowed the most appalling errors to appear in the printing of the illustrations. Five of the tables in the book have had all data in them omitted in printing. In a tardy attempt at correcting this error, the publishers have issued with the later copies offered for sale an eight-page 'errata sheet', but with incredible incompetence these have been printed in a way that makes it impossible to substitute them for the faulty pages, as each has been backed on to another, with p472 backing, for example, p516. It can only be hoped that a new printing can put such a stupid blunder right.

P. C. Sylvester-Bradley

P. C. Sylvester-Bradley is F. W. Bennett Professor of Geology in the University of Leicester, UK.

Reaction kinetics

The Organic Chemistry of Electrolyte Solutions. (Interscience Monographs on Organic Chemistry.) By John E. Gordon. Pp. xxi+554. (Wiley-Interscience: New York and London, December 1975.) £15.35.

The Electrolyte Chemistry of Organic Solutions? No, that will not do either; the title is strange and ill-chosen.

The book's aim, according to the author, is to provide the organic chemist with everything he needs to know about electrolyte solutions, to treat all important solution chemistry measurements in one of its three chapters, while avoiding treating in detail aspects accessible through books such as Robinson and Stokes, and Harned and Owen; and therefore to graft on to the traditional physicochemical framework more 'chemical' information lacking in the great books from non-traditional sources such as vibrational and nuclear magnetic resonance spectroscopy. In less pretentious phraseology, to up-date the standard texts by including the important advances over the past 20 years made through the application of spectroscopic techniques. This is not the first attempt to do so in spite of the fly-leaf's claim, nor does the book seem to have been produced any quicker than a multiauthored volume, as the Series Editor claims, for the literature coverage is complete only to mid-1973 and cuts off in August 1974; and the book was not published until the end of 1975.

The three chapters referred to above are called Salt Effects, Ion Solvation and Ion Association, which are not mutually exclusive categories, as

the author realises. Each chapter concludes with a lengthy section discussing applications to kinetic studies, thus revealing the true interest of the author and his intentions. Has he succeeded? To a very large measure, he has. The book is no paste and scissors concoction, but scholarly and nearly always sound in approach and explanation if not in balance and selection of material. For, in discussion of theoretical conductance equations, only the earlier work of Fuoss is discussed, neglecting his later contributions and those of Prue, Pitts and Justice amongst others. Similarly the discussion of *p*H, under the heading of 'Single ion activity coefficients', returns unnecessarily to the 1920s treatment; and the widely adopted important NBS method is described as "based on yet another convention". Order of introduction of new concepts could have been better conceived. Terms which will surely puzzle the uninitiated when they first appear often receive more detailed explanation many pages later. The book is well illustrated with figures and diagrams drawn from the literature but not always too well associated with textual explanation. Nevertheless, physical organic chemists and others should find much of value in this book as a source book to the extensive literature on electrolyte solutions. It should help to continue to advance the interpretation of reaction kinetics in organic solvents, a subject which has progressed a long way since ion-pairs and solvated ions were first invoked to explain kinetic data when mechanistic explanation was otherwise at a low ebb.   **A. K. Covington**

A. K. Covington is Reader in Physical Chemistry, University of Newcastle upon Tyne, UK.

Cell split

Cell Division in Higher Plants. (Experimental Botany: An International Series of Monographs, Vol. 7.) Edited by M. M. Yeoman. Pp. x+542. (Academic: London and New York, April 1976.) £16.50; $41.

KNOWLEDGE of the cell division process and its control in plants has developed rapidly in recent years from observations made in a diversity of research fields. Dr Yeoman's concept behind this volume was clearly that this scattered material had to be brought together and presented in a developing sequence so that this recent progress could be fully appreciated and the as yet outstanding problems critically identified. The Botany Department at the University of Edinburgh has been one of the main centres of current research on cell division in plants, and

members of this department have obviously played a critical role, under Dr Yeoman's astute editorship, in the realisation of this volume. Professor R. Brown, in an introductory chapter, identifies the problems posed by the organised cell divisions in plant meristems and develops, in a thought-provoking way, models which will clearly guide future research. A group of chapters then deal with the process of cell division both in somatic and reproductive cells. A. F. Dyer contributes two chapters on mitosis which deal in a most lucid way with mitotic cycles and the origin and consequences of mitotic modifications and errors. A parallel chapter by M. D. Bennett (Plant Breeding Institute, Cambridge) deals with meiosis. M. M. Yeoman and P. A. Aitchison summarise our present very limited knowledge of the molecular events of the cell cycle, and Rachel M. Leech (York) our similarly very imperfect understanding of plastid replication.

The second major section of the book considers cell division in relation to the generation of form. The very intensive studies on the root apex are surveyed by F. A. L. Clowes (Oxford). This is followed by chapters on the shoot apex (R. F. Lyndon), leaves (J. E. Dale) and cambium (I. D. J. Phillips, Exeter). W. A. Jensen (Berkeley, California) contributes a disappointing short chapter on cell division in embryo development. This section of the book is completed by an interesting survey of unorganised cell division and morphogenesis in tissue and cell cultures by A. W. Davidson, P. A. Aitchison and M. M. Yeoman.

A final section headed Summary and Perspectives and written by Dr Yeoman suffers from its extreme brevity (4 pages) so that it is little more than a list of central themes and a signposting to the various fields of research (covered in the preceding chapters) which are contributing to these themes. Some critical discussion of perspectives would have been of real value here.

Setting aside these minor blemishes the volume is timely, well conceived, and scholarly written. It fills a real gap in botanical literature. In general the chapters are uniform and appropriate in standard so that they will be of value to established scientists looking for a well documented survey but equally appropriate for advanced undergraduate reading. The authors and press are to be congratulated on the excellent plates and informative line diagrams many of which have been specially prepared for the volume.

H. E. Street is Professor of Botany at the University of Leicester, UK.

Energy past and energy present

Man, Energy, Society. By Earl Cook. Pp. xi+478. (Freeman: San Francisco and Reading, May 1976.) Cloth £10.40; paper £4.50.

THE availability of energy is clearly a key element in the history of civilisations, the size, form and behaviour of societies and the choices open to them. Following in the steps of Fred Cottrell's remarkable *Energy and Society* (1955), the geologist and geographer Earl Cook here re-explores this fascinating set of connections. The result is a valuable, broad introduction to 'energy' in a historical, social, geographical and economic setting. The sweep is immense, ranging from the emergence of agriculture to future energy alternatives of varying sociopolitical stability. The approach is often refreshingly catholic: thus, a major section on the global distribution of energy resources starts with arable and pasture land; food (and its getting) commands as much attention as the major fossil fuels; the ethics of resource depletion and the sociology of control of energy use are discussed as thoroughly as the usual technical and economic topics. One consequence is to make the book a valuable source of inaccessible statistics and data, such as the efficiency of early machines; the total system energetics of transport, food production, mining and other industrial activities; and the rising energy and other costs of winning lower grade mineral and fuel resources.

Although useful up to a point, any uni-dimensional view of the world can all too easily be taken too far into empty truisms and gross overstatement. Cook all too often falls into these traps, walking dangerously close to a pure 'energy theory of value'. Statements such as "a doubling of living level requires approximately a doubling of available energy" (p190); that if energy use per capita is not increasing then economic development is reversing (p218); and that the gap between developed and underdeveloped regions in per capita energy use is widening (p18), underpin many of the book's theses, yet are demonstrably false. Nor is it exactly helpful, in the absence of any sustained discussion of overt political factors in the control of energy or of society, to come across remarks such as "high energy man seeks diversion in sports, business, drugs, sex, rioting, and crime" (p221), or that the Crusades could not have happened without the mobilisation of energy surpluses in Northern Europe "reflected in horses, armour and men"

(p195). Yet read with a wary eye and a few pinches of salt, this is nevertheless a valuable book as both a thought-provoker and source of information.

Energy Resources and Supply. By J. T. McMullan, R. Morgan and R. B. Murray. Pp. xii+508. (Wiley-Interscience: London and New York, March 1976.) £12.50; $27.50.

FEW of the 'broad survey' books on energy that are now flooding the market focus with such admirable clarity, thoroughness and wide scope as does this on the hard-nosed physics and engineering of the subject. Aimed at university courses and the more numerate specialists, the emphasis is predominantly on techniques and their physicochemical basis—in many ways a refreshing change that helps fill an important gap. There is also a strong bias towards the 'mainstream' supply and conversion technologies, with about half the book devoted to resources, extraction, processing and characteristics of the fossil fuels and the nuclear fuel cycle, both fission and fusion. Opening chapters survey the energetics of the biosphere-atmosphere system and photosynthesis, whereas there are relatively sketchy chapters on solar energy, other renewable sources, storage, energy-in-use and (with proper enthusiasm) the heat pump.

The coverage and density of information is impressive. Yet there are curious gaps. For example, there is much about peat as a large 'fossil' resource but nothing about the vast annually renewed fuel sources in (tropical) estuarine biomass; in a long section on nuclear reactors there is the scantiest reference to comparative efficiencies of fuel use; the account of solar collectors bristles with algebra but there is hardly a word about overall system design or integration of solar with other ideas (including storage and heat pumps), the keys to success in this area. More seriously, there is such a determined avoidance of almost everything but physics and engineering that the real world sometimes seems light years away. There is almost no mention even of costs, and the broader economic and social aspects of energy are confined to a single chapter of six pages. The total misunderstanding of the energy situation, needs and constraints of the undeveloped world, revealed in the final pages, is no less than appalling in a book which in many ways deserves to become a basic text for undergraduate and graduate students in the physical, engineering and environmental sciences. **Gerald Leach**

Gerald Leach is a Senior Fellow of the International Institute for Environment and Development, heading a program on alternative energy strategies for both the industrialised and less developed world.

Plant ecophysiology

Physiological Plant Ecology. By W. Larcher. Translated by M. A. Biederman-Thorson. Pp. xiv+252. (Springer: Berlin and New York, 1975.) DM 46; $18.90.

IN revising and translating into English the original German text *Okologie der Pflanzen*, the opportunity has been taken to adopt a more accurate title, which is supported in the Preface by an adequate description of the subject matter and aims of the book. Ecologists urgently seeking physiological information relevant to field situations for teaching and research purposes, invariably have to search a voluminous literature. Professor Larcher is to be congratulated on making this task so much lighter, by producing a concise account of many important aspects of plant ecophysiology.

Inevitably, the topics covered reflect the authors's own research interests and the limitations of space and cost. The approach adopted of portraying the development of the subject in the choice of illustrations and tables is ex-

tremely interesting. Much of the material is new and valuable syntheses have been made in a number of tables, yet in certain sections, especially those on nitrogen and mineral elements, the treatment is somewhat out-of-date. Under the heading 'Dry-matter Production' (p63) the section on growth analysis would greatly benefit by additional references to recent alternative articles and texts. There are very few obvious errors in the text: (cf p000) should be (cf p134) on p54 and (cf p000) following Id=direct solar radiation (p191) should be omitted from this revised translation. I would prefer to see Leguminosae used on pp94, 101, 115 and 119 instead of Fabaceae.

The book is a valuable source of reference to articles normally hidden away in the German literature and it is to be regretted that the current rates of exchange will put it beyond the pockets of most undergraduates.

K. Taylor

Dr Taylor is a lecturer in the Department of Botany and Microbiology at University College, London, UK

obituary

Jerome Vinograd was born February 9, 1913 in Milwaukee, Wisconsin, and died July 3, 1976. After undergraduate work at the University of Minnesota, he studied colloid chemistry with H. Freundlich from 1931 to 1935, first in Berlin then in London. He completed his doctoral work with J. W. McBain at Stanford from 1937 to 1939 and was associated with the Shell Development Co. from 1941 to 1951 where he worked mainly on problems of surface films and colloids. At that time, he gave up a secure industrial career and came to the California Institute of Technology because of his intense desire to work in the exciting new area of molecular biology. His early work at Caltech dealt mainly with the physical chemistry of proteins.

His first outstanding contribution to molecular biology was the invention, in collaboration with Meselson and Stahl, of the method of equilibrium density gradient centrifugation of nucleic acids in caesium chloride solutions. This method has been elaborated in Vinograd's and other laboratories to take advantage of the effects on buoyant density of base composition, denaturation, alkaline titration, binding of metal ions and of dyes, and hydration. All told, equilibrium buoyant banding has been one of the key techniques in the explosive development of the nucleic acid side of molecular biology since the mid 1950s.

Vinograd's outstanding work in the past 12 years has been in the study of closed circular DNA. The distinction between supercoiled closed circles and open circles was recognised in 1965. The ethidium bromide method of buoyant banding for the isolation of closed circular DNA was invented in 1967. This method, which makes it possible to analyse for and to isolate closed circular DNA in the presence of massive quantities of linear and open circular DNA, is widely used, and is one of the main reasons why there has been such exciting progress in the study of

closed circular DNAs in different kinds of cells.

Later work dealt with the properties of mitochondrial DNA from malignant cells and with the study of the replication of mitochondrial DNA, initiated by the discovery of D-loops in Vinograd's laboratory. More recently his students have made several important contributions to the studies of the properties of the nicking and closing enzyme which relaxes supercoiled DNA while leaving it covalently closed. The Vinograd group as well as the groups of Keller at Cold Spring Harbor and Wang at Berkeley observed that one can use gel electrophoresis and relaxation by an enzyme to count the number of turns in a closed circular DNA, and that there is a Boltzmann distribution in the number of superturns in molecules which are closed, under equilibrium conditions.

Vinograd was, by early training and in his approach to molecular biology, a physical chemist. He had a flair for recognising when an anomalous and unexplained observation, if subjected to fundamental physical chemical analysis, would lead to an unexpected and important result in molecular biology.

I have seen the special Vinograd touch many times. A simple example is the development of the velocity band centrifugation method by Vinograd, Bruner, Kent and Weigle in 1963. Shortley before, Jean Weigle had discovered that he could layer a dilute solution of viruses in aqueous buffer on to a sucrose solution (not a gradient) in a centrifuge tube, centrifuge and get a good sharp virus band. Vinograd was puzzled as to why the band was sharp, and reasoned that there must be some effect providing convective stability. He recognised that there had to be a self-generating (by diffusion) density gradient to provide convective stability; a careful study then led to the development of this general and widely used method.

I remember vividly a seminar at Caltech in late 1966 or early 1967 when J. B. LePecq described his studies on the binding of ethidium bromide (Etd Br) to DNA. An important point was that, unlike the common acridine dyes, there was a reasonable amount of binding at high salt concentration. Vinograd pointed out at the discussion which immediately followed that if the dye ion bound in 6 M CsCl it would cause a large shift in the buoyant density of the DNA because it would displace a Cs^+ ion. Experiments by W. R. Bauer (then a graduate student) showed that Etd Br would indeed decrease the buoyant density of DNA, but that the shift was much larger for a relaxed than for a closed circular DNA. On learning of this result, Vinograd immediately perceived the correct explanation in terms of the topological constraint on the unwinding of closed circular DNA, thus leading to the development of an extremely useful method for isolating closed circular DNA, as well as for studying the free energy supercoiling.

He suffered a major heart attack in 1954 and a second one in 1969. He accepted the resulting restrictions on his overall activities philosophically. But his condition did not affect the intensity with which he devoted himself to his scientific work. I remember him through all these years being in the laboratory regularly on evenings and weekends discussing and analysing experimental data in painstaking detail with his students, seeking a fundamental explanation for unexpected and unexplained results. His students and colleagues will miss his penetrating insight into technical problems and his wise counsel on general policy issues.

Vinograd was made a member of the National Academy of Sciences in 1968, and received numerous awards. He is survived by his wife Dorothy, and his two daughters Julie and Deborah by a previous marriage.

Norman Davidson

Person to Person

The Beilby Medal and Prize will be made to a British scientist for work in any field related to the special interests of Sir George Beilby (chemical engineering, fuel technology or metallurgy). Apply to The Convener of the Administrators, Sir George Beilby Memorial Fund, The Royal Institute of Chemistry, 30 Russell Square, London, WC1B 5DT.

The Commission of the European Communities is sponsoring travelling Fellowships for obstetricians, neonatologists and research workers who are actively engaged in perinatal monitoring. The successful applicants will spend three weeks in a centre for perinatal monitoring within the EEC, outside their own country. Applications to Commission of the European Communities, Directorate-General Research, Science and

Education, X11/C-1, 200, rue de la Loi, 1049 Brussels.

Address and details of the work of Rose Selavy on stellar lightning (ref. Brecher, K., *Nature*, **261**, 542; 1976) would be appreciated by Mr E. W. Crew, 26 St David's Drive, Broxbourne, Herts, UK.

There will be no charge for this service. Send items (not more than 60 words) to Martin Goldman at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

Still plenty for the BA to do

ANOTHER meeting of the British Association for the Advancement of Science (BA) comes and goes, and yet again the question arises, do we still need the BA, and if so, for what purpose?

Certainly, the annual meeting is not the only activity of the BA. Throughout the year there are study groups, science fairs, schools conferences, visits, publications, and so on, and it is indisputable that much of value is achieved by all this. But a lot of energy goes into the annual gathering, at which a good accumulation of speakers is assembled. To judge by the size of the audience at many of these talks, this effort is simply not being repaid by enough public interest to warrant an endless annual commitment. Is the fault with the BA and its organisers or is it elsewhere?

It would be easy to blame the BA. "Meet Britain's leading scientists" ran the headline on the poster put about locally in Lancaster. Directly beneath it was a large picture of the association's irrepressible and telegenic executive secretary, Magnus Pyke. Some of Britain's leading scientists, whose contributions are essential if the BA is to survive, might reasonably wonder whether the message should not have read, "Meet Britain's best known scientist".

The media do not help. Armed with copious preprints of lectures, correspondents find it all too easy to turn in large quantities of uncritical copy of the "said Dr Smith" type, which manages at once to convey the impression both of a lack of authority and of exaggerated claims. This conceivably does more harm than good in helping the public to a better appreciation of the achievements and limitations of science; it conceivably also scares away potential friends of the BA among the scientific community.

But it is an easy escape to blame the BA, its slightly amateurish image, its press coverage, for a major deficiency in us, the scientists. The BA still manages to persuade a good number to come and deliver lectures, but with many, no sooner is the lecture delivered than it is a case of up and away, probably to be back in the laboratory as soon as possible. Maybe there are pressing engagements elsewhere, but perhaps we have things to learn from a diverse audience every bit as interesting as they have to learn from us. And, of course, the number of practising scientists who go to BA meetings if not invited to speak is all too small. As a result, the annual gatherings seem to lack the necessary critical mass of those actually producing the subject matter. Such a cavalier attitude towards specialist conferences would, of course, be unthinkable.

It may be argued that scientists have better things to do than spend several days adding to their general scientific knowledge. If there was much evidence that scientists used other ways of preventing themselves from getting caught in a specialist rut, then that might be a perfectly valid argument. But we are dubious that the average research scientist is anything like as well read as he or she should be to take full advantage of all the intellectual opportunities that science has to offer. And we would not be surprised if this narrowness is significantly more pronounced in the United Kingdom than it is in many other parts of the world, no doubt largely as a result of an educational system which, for better or worse, produces single-minded, specialist experts at the age of 24.

There was a time, and not too long ago, when this was something to be proud of. But with changing economic circumstances people are beginning to ask whether, without too much lowering of the standards of scholarship, it might be possible to ensure that the scientist's interests are not quite so intensely focussed. The BA should undoubtedly have a role to play in this by providing an arena in which scientists can learn from each other, from administrators, from politicians and even from taxpayers. This requires a broader commitment, of a kind which there once was, but which is now lacking. Is there any chance that Britain's scientific community might regain it in the future? □

National Air and Space Museum, Washington, DC

America's history lesson

Chris Sherwell sees the Smithsonian's latest spectacle in Washington, the National Air and Space Museum

TO glide from Washington's white heat of late summer, past the imposing pink marble and tinted window facade of the National Air and Space Museum, and on into the air-conditioned splendour of an enormous hall dedicated to the milestones of aviation, is something of an experience. For there, in just one room, is the Wright Brothers' Kitty Hawk; Lindbergh's Spirit of St. Louis; the first plane to break the sound barrier; and the X-15, which has flown at Mach 6.72. And that is just on the 'Air' side. For 'Space', and in the same room, there is a replica of Sputnik and a duplicate of Explorer I; John Glenn's Mercury capsule, Friendship 7; Gemini 4, which carried the first US space walker; a replica of the Mariner 2 interplanetary probe to Venus; the Apollo 11 command module, Columbia; and the first piece of "touchable" lunar rock. It is all a remarkable introduction to a remarkable display.

Nearly three million people have already traversed that hall, and the museum opened only eleven weeks ago; on one particular day, 82,000 people decided to visit. All seek to be informed and educated in an interesting and entertaining way about the history of aerospace. Most leave satiated. The man who piloted 'Columbia' on that memorable moon landing flight, Michael Collins, is the museum's director. He acknowledges that there is no accepted view of what a museum is supposed to do, but at his disposal is a team of 250, a vast archive, a huge 'spacearium', an enormous theatre with a 55-foot high screen, scores of audio-visual aids and, of course, hundreds of artefacts—which means aircraft and spacecraft. The result is a 23-section history of flight, beginning with balloons, and ending with the Universe, with digressions into flight and the arts, air-traffic control and the benefits of flight on the way.

Although the balance of the museum's overall display is in favour of Air rather than Space, the most spectacular exhibits are the space-related ones. The Skylab Orbital Workshop and Multiple Docking Adaptor, together with the giant Minuteman and other missiles, dominate the second major hall, the Space Hall. Next to these are the Apollo–Soyuz spacecraft and docking module; nearby is a Lunar Module, with the Orbiter and Surveyor satellites suspended above. A room dedicated to the Moon landing project includes a complete rundown on all the crews of manned US spacecraft, a full-size mock-up of the Lunar Module cockpit, displays of experiments performed on the Moon (along with the Lunar Roving Vehicle) and several samples of lunar rock.

None of this could have happened without rockets like the Saturn V, at 353 feet so high that there is room in the museum for only one of its main engines; mirrors have to be deployed to give some idea of the overall size. Rooms on rocketry and rocket history accord due prominence to Goddard, Oberth and Tsiolkovsky, but the television series *Star Trek* is not forgotten either. The superb satellite room has communications, Earth monitoring, science and weather satellites, but no spy satellites. Collins would like one, but no one acknowledges they exist, and no one has recovered one.

Air sections too have their own attractions and distractions. Apart from the World War rooms, there is, for the more ghoulish, a constantly running film of the last flight of the Hindenburg and film of the more spectacular of the crazy acrobats who flew on planes rather than in them. In the Sea-Air Operations rooms visitors can stand on the bridge of an aircraft carrier and watch planes land on the deck, or alternatively (and more alarmingly, since there is no attempt to explain the military concept behind an aircraft carrier) join the pilots of the planes themselves as they go on a short 'mission'. Elsewhere, certain technical principles are exceedingly well demonstrated. There are explanations of the propeller, the turbofan engine, jet propulsion and, in the Flight Technology room, of supersonic flight and even of flight itself.

As always, the problem, even in an aerospace museum, is space—that is, the lack of it. The museum is, in fact, only two-thirds of its originally proposed size. Thus, there has to be some disappointment for everyone. In the third major hall, the Air Transportation Hall, for example, a Douglas DC-3 hangs majestically, "the most important single aircraft type in the history of air transportation". The same could not be done for what may turn out to be the most important planes since—the Lockheed C-5A and the Boeing 707. The problem, of course, is that there is no room for what would need to be another airport in the centre of Washington.

How, then, did Collins and his team decide priorities? "It's an imperfect process", he says; some categories—First and Second World War aviation, for example—chose themselves. One problem, revealed by an early survey of audiences in four of the halls, is that people by-pass important exhibits in their desire to see particular attractions like the Spirit of St. Louis. That exhibit is already the most popular, and Collins suggests that this is something to do with Lindbergh himself: people can relate to his "one-man show" a lot better than they can to the space programme, where there is "a cast of hundreds of thousands".

In fact, although the enormity of the US space effort is more than adequately conveyed by the sheer size of some of the exhibits, the impact which the aerospace industry, indeed flight itself, has had on American people and Western society generally is perhaps insufficiently emphasised. Partly, this is a problem facing any museum, where the idea of history as events, turning-points and personalities finds its greatest expression. But it is also a matter of perspective.

Take one particular personality, Howard Hughes—surely the *eminence grise* of US political and economic life. On the tiny Giants of Air Transportation exhibit the briefest of blurbs says only: "Howard Hughes for many years was the guiding force behind TWA and worked on the design of the Lockheed Constellation". In the larger Flight Technology room, the Hughes H-1 Racer is the centrepiece, and is represented, proudly, as "a major milestone on the road" to Second World War fighters like the the Grumman Hellcat, the Japanese Zero and the German Focke-Wulf FW 190. And in the Benefits of Flight room, Hughes Aircraft and the other major aerospace corporations like Boeing, Lockheed, Rockwell, Northrop, Grumman and McDonnell Douglas, merit just a mere mention on a backdrop list. Nowhere in the museum can the links, if any, between war, politics, the economy and the major corporations be more than guessed at or presumed.

Crucial decisions of the present—in the case of the US, those concerning the so-called "Sale of the Century" of fighter planes, the B-1 Bomber or the Boeing 7X7 and 7N7—receive little emphasis. There are some elements of topicality—a full-scale model of the Viking Lander, for example. But the biggest gap occurs with the supersonic transport, or SST, of which there is not even a passable model. The decision not to go ahead with this in the USA was, in the view of many, a defeat for science and technology. Not to have an exhibit is a defeat for a museum which aims to look to the future as well as the past, and which actually manages this, if somewhat disappointingly, with the Space Shuttle. Collins himself admits that this may be a weakness, and even allows that, as far as topicality is concerned, the museum "does not do that very well".

Not that the museum fails totally to overcome the problem of presenting history in terms of events. But it does go only a little way towards describing the social impact flight has had. The Benefits of Flight rom is an acknowledgement that the major exhibits do not offer aerospace automatic self-justification. There the view is expressed—near a deactivated atomic bomb—that flight has contributed to peace rather than war, at least between the major powers ("the sword over Damocles' head"). Exhibits in the same room refer to work on the Earth's resources, to scientific research, to agriculture, to the weather, to communications and so on. A juke-box blaring out Elton John's "Rocket Man" and Frank Sinatra's "Come Fly with Me" spotlights the cultural impact; so does the list of additions to our vocabulary, and the whole Arts room.

But in the areas where the greatest human transformation has been wrought—in population mobility, in the way people think of time and space and, above all, in the way production is organised—the museum shows its greatest weaknesses. How to remedy this? Perhaps the answer lies in the spacearium and theatre, which currently come closest to surmounting the difficulty with the presentations "Cosmic Awakening" and "To Fly", both pitched to a mass audience, and a mass American audience at that.

Above the two floors of display, together with the staff offices, is the library, available by appointment for any researcher to use. It has provided the main documentation for the show below. Collins says he has sought neither to editorialise nor to impose too much uniformity through excessive analysis. He favours an element of surprise instead, treating some subjects more seriously and some more whimsically than others. He agrees that the aim must be to make a presentation that allows an audience to draw its own conclusions, rather than one which makes particular preconceptions and makes certain conclusions inescapable. He acknowledges that some things need to be dressed up just to catch attention, but would hope that the inevitable built-in bias of any museum is in this case acceptable.

Apparently, it is: if the anti-space or anti-business lobbies in the United States believe that he has in fact failed in his task of educating a curious public, their views have gone largely unrecorded. Collins and his staff are pleased with the press they have received. The only serious regret about such a venture must be that it is a National Air and Space Museum, and not an international one. □

ESA airs itself

Last week, the European Space Agency displayed itself at the Farnborough
Air Show in Britain. **Allan Piper** reports

IN solid commercial terms, this year's Farnborough International Air Show brought relatively little joy to the world's aerospace industries, with firm orders for hardware considerably down on recent years. To the many large corporations affected—companies such as Rolls-Royce and Westland from Britain, Aerospatiale and VFW-Fokker from Europe, and Boeing, Lockheed and McDonnell Douglas from the US— the cutback is no less unwelcome for all that it was expected and is seen as only temporary. But few of the contractors present will regard the latest Farnborough as a complete failure. In the first place, the long-term future of the aerospace industry seems secure enough, and this year's record crowds again proved the show's worth as a massive public relations exercise. Second, and far more important, the get-together encouraged a measure of serious discussion on what has become a vital issue for world aviation—international collaboration.

With the enormous expense now involved in the design and development of most civil and military aviation hardware, it is scarcely surprising that collaboration emerged very early during this year's show as the new watchword for aerospace. In Britain, attention focused particularly sharply on planned Anglo–US discussions announced by Gerald Kaufman, the UK Industry Minister.

But for the 12-nation European Space Agency (ESA), prominently represented at Farnborough, collaboration is an already well-established principle. Since its launching almost 16 months ago ESA has put no less than eight scientific satellites successfully into orbit, working with three giant consortia involving many of Europe's aerospace contractors.

While that prolific record itself speaks volumes for the success of European cooperation, early discussions on joint ESA–NASA ventures have ensured that broader collaboration will not go by the board either. The Spacelab project, already under way, represents ESA's largest scientific contribution to the NASA space shuttle programme, planned for the late 1970s and 1980s. Next month, ESA officials are expected to approve funds for another joint project with NASA, the Large Space Telescope. And many of the other new projects in the ESA pipeline will play important roles in forthcoming international programmes.

Meanwhile, Farnborough provided

ESA with an ideal opportunity to stamp its presence on the public's mind. Operating comfortably on a current annual budget of $600 million, the agency has much to offer in the way of eyecatching space technology. Triumphs have already been notched up with the ESRO, HEOS and COS B satellite programmes, and ESA has an equally impressive timetable drawn up for the next four years or so. New ESA projects include:

● OTS, the Orbital Test Satellite, scheduled for launching in mid-1977. Primarily a demonstration model for the European Communications Satellites (ECS) programme, OTS is nonetheless adaptable for various missions. The basic service module can, for example, carry weather forecasting equipment just as effectively as a telecommunications payload. The first operational ECS's will provide around 5,000 telephone circuits and two wideband television channels along with data transmission and teleconferencing services. During Farnborough a £900,000 design contract for ECS-1 was placed with MESH, one of the European consortia.

● METEOSAT, a long range weather forecasting satellite, scheduled for launching next year. METEOSAT will provide Europe's contribution to the Global Atmospheric Research Programme and the World Meteorological Organisation's later World Weather Watch. It will also fit into a global coverage involving Japan, the Soviet Union and the US.

● GEOS, the world's first scientific geostationary satellite, will monitor the magnetosphere. Scheduled for launching next year, it will play a major role in the International Magnetospheric Programme.

● IUE, the International Ultraviolet Explorer, a joint venture between NASA, the UK Science Research Council, and ESA, to be launched next year. ESA will contribute the solar-cell array for the satellite, and will design, build and operate the ground station near Madrid in Spain.

● ISEE-B, the International Sun–Earth Explorer, part of another NASA–ESA collaborative project. ESA's ISEE-B will be launched in tandem with NASA's ISEE-A next autumn.

● MAROTS, a shipping communications satellite scheduled for launching early in 1978. The payload will sit on an OTS service module.

● AEROSAT, an aeronautical satellite for ground to air communications on
Earth. Two AEROSATs will be launched into geostationary orbit at the end of 1979 and beginning of 1980.

● EXOSAT, an X-ray astronomy satellite that will monitor cosmic X-ray sources. Along with GEOS, IUE and ISEE-B, EXOSAT will be a purely scientific spacecraft. It will be launched in 1980.

● Spacelab, the star of them all. A re-usable pressurised space laboratory, Spacelab will house scientists and engineers working in shirtsleeve comfort. A major component of NASA's space shuttle programme, it will become operational during the 1980s.

● Increasing congestion in the international queue for NASA's launching facilities, which is likely to become worse as NASA steps up its own requirements, has led ESA to develop a heavy launcher, Ariane, for itself. Designed to lift satellites weighing around 800 kg, it could prove crucial to the ECS programme. Ariane's four qualification shots, planned for 1979 and 1980, will be from the permanent launching base in French Guiana. □

Approaching scientific issues

While the Ford administration has been setting up the White House Office of Science and Technology Policy (see page 184), Jimmy Carter's campaign organisation has been establishing links with prominent members of the scientific community. Colin Norman reports

THE campaign between Gerald Ford and Jimmy Carter for President of the United States officially kicked off last week with a round of speeches from the two candidates and their Vice-Presidential choices. Nobody said anything about science, but then nobody really expects scientific issues to play much of a role in this campaign. "Science", as one adviser to the Carter campaign pointed out, "is not exactly the most burning issue in the public mind". Moreover, there's little discernible difference between Republican and Democratic policies for research and development.

But that doesn't mean scientists will play no part in the campaign. Far from it. In fact, it has become something of a tradition for large number of scientists and engineers to shed their usual non-partisan roles and enter the fray on behalf of one candidate or another, and this year will be no different. An extra facet in this campaign, however, is that the Carter organisation has been actively seeking advice from a diverse array of scientists, and that advice has been flowing in quite freely.

It is coming from a very loosely knit science policy task force, whose activities are coordinated by Lewis Branscomb, chief scientist for IBM, former director of the National Bureau of Standards and a well respected figure in science policy circles. Other members of the task force include such equally prominent figures as Harold Brown, President of California Institute of Technology, Harvey Brooks, Professor of Technology and Public Policy at Harvard, David Baltimore, a Nobel Prizewinner from MIT, and George Low, President of Rensselaer Polytechnic Institute.

The science policy task force mirrors similar units advising Carter on a vast range of other issues. It is a very informal, *ad hoc* arrangement involving members who rarely, if ever, meet. Instead, they draft policy papers which are sent to the Carter campaign headquarters, to be used as Carter's staff sees fit in drawing up position statements and speeches. As one task force member noted last week, "we haven't exactly got much power in formulating

the policies". This conforms with Carter's well-established approach of seeking opinions from a diverse array of individuals before enunciating his own positions. In foreign policy matters, for example, his advisers include people whose perspectives differ so widely that they must be offering all sorts of conflicting advice which the Carter campaign organisers are filtering and stitching together.

Branscomb said last week that he first became acquainted with Carter late last year, and that he was "impressed with (Carter's) intelligence and approach to scientific issues". Branscomb said that he personally favoured Carter's nomination as the Democratic candidate, and agreed to head the science policy task force when Carter approached him. A measure of the generally non-partisan nature of science policy here is that Branscomb was also a member of a committee advising the Ford administration on an agenda for the new White House Office of Science and Technology Policy (OSTP).

Branscomb has repeatedly emphasised the informal nature of the task force, and its broad membership. Many people, he said, are simply being asked for their views on issues, and their involvement carries no implication that they would necessarily endorse Carter's candidacy. "We are trying to make a contribution to good government," he told *Nature,* and added that the task force is "trying to avoid being an elitist, exclusive club with an inside track".

With Carter already commanding a formidable lead in the public opinion polls, it's clear that the task force is looking beyond November, attempting to lay the groundwork for the first few months of a Carter Administration. In that regard, there has been some speculation that if Carter is elected he will ask Branscomb to be his science adviser and the Director of OSTP. Asked last week whether he would accept such an offer if it is made, Branscomb said the possibility has never been discussed with the Carter organisation, and that he prefers to cross that bridge if he comes to it.

In spite of all the advice flowing into the Carter camp on science policy, so far there is little major difference between the two parties on scientic matters. As far as the party platforms are concerned, for example, though the Republicans devote a few paragraphs to science and technology, the wording is not at all controversial, and could easily have been part of the Democratic manifesto.
Ford, disastrous

Carter, looking forward

The Republican document states, for example, that "every aspect of our domestic economy and well-being, our international competitive position, and national security is related to our past and present leadership in basic and applied research and the development of our technology. But there can be no complacency about our continued commitment to maintain this leadership position". The Democratic platform simply makes no reference to such matters.

Some differences are, however, beginning to emerge between the two candidates on energy and environmental matters, which have some bearing on research and development.

In a speech before the National Press Club last year, for example, Carter attacked "President Ford's disastrous energy policy", which he described as the "Ford/oil industry energy policy", and claimed that it would eventually lead to higher energy

prices and greater reliance on oil imports. He said he was looking forward to the opportunity to formulate his own energy policy, in an atmosphere devoid of crisis. Though he hasn't been too specific about his proposals, Carter has since suggested several times that he wants to see more emphasis on conservation, more spending on solar energy, and more reliance on coal. He has also attacked the Ford Administration's plans to push development of a synthetic fuels industry.

The chief difference between the Carter and Ford energy policies lies in the area of nuclear power. In a statement made to a United Nations conference last May, Carter suggested that dependence on nuclear power should be held to the minimum necessary, and he has said that he would reassess the priority being given to the liquid metal fast breeder reactor—the most expensive single energy research and development project supported by the Ford administration. He has, however, stopped short of calling for a moratorium on nuclear power, and he refused to support the California initiative calling for a virtual halt in the development of nuclear power there. (The initiative was defeated in a state-wide referendum last June.)

As election day approaches, science and technology are unlikely to figure very prominently, simply because they do not figure very prominently among the issues about which people are concerned.

If that is a source of encouragement for scientists, it is largely because of the prestige they enjoy. □

AFTER a series of unexpected and often bizarre delays, the newly-re-created White House Office of Science and Technology Policy (OSTP) is finally getting down to business, four months after it was legislated into existence and—if the opinion polls are to be believed—only a few weeks before the Ford administration is scheduled to make its political exit. Even though the administration's days may be numbered in double figures, however, OSTP is being established as if its working arrangements will endure well beyond next January's Presidential inauguration.

H. Guyford Stever, who heads the office and who also holds the title of Science Adviser to the President, said in an interview last week, "I'm not expecting a change of administration. And neither is the President". Accordingly, he is busy recruiting staff, hiring consultants and establishing committees, which means that Jimmy Carter, if he is elected, will inherit a functioning science policy office and some top-level committees whose members would be difficult to replace.

Although legislation establishing the office was signed into law by President Ford on May 11, after taking more than a year to pass through Congress, the OSTP's debut was delayed by an unexpected dispute over the appointment of a director. It had long been rumoured that Ford would nominate Simon Ramo, head of the giant aerospace and defence consortium TRW, as his science adviser and director of OSTP. But the nomination was never made, apparently because Senator Kennedy's office insisted that Ramo would have to divest his holdings in TRW before the Senate would confirm his appointment. Ramo decided that, since the polls all pointed to a resounding Ford defeat in November, it wasn't worth the price to be a science adviser for only a few months. Attention then turned to Guy Stever.

An aerospace engineer and former President of Carnegie-Mellon University, Stever has been Director of the National Science Foundation (NSF) since 1972 and part-time White House Science Adviser since mid-1973, when Mr Nixon scrapped the old Office of Science and Technology and consigned some of its functions to the NSF. Stever would therefore seem a logical choice for the full-time post of Presidential Science Adviser. But, when news of his impending nomination filtered out, four right-wing Republican Senators warned Ford that they would oppose the appointment. Led by Senator Jesse

Man at the top

H. Guyford Stever

Helms, they issued a statement criticising Stever's stewardship of the NSF, resurrecting many of the disputes which have swirled around the NSF's education programmes for the past year.

The opposition surfaced while Ford was locked in his neck-and-neck with Ronald Reagan for the Republican nomination. Stever, mindful of the fact that Ford was trying to steer clear of fights with the party's right wing, suggested that his nomination be reconsidered and the matter was put on the back burner for nine weeks. Then, when Ford had the nomination virtually locked up, Stever's nomination was sent to the Senate early in August and swiftly approved with only token opposition.

Stever said last week that he agreed to take on the assignment with the understanding that he wouldn't remain long after January, no matter which administration takes office.

The legislation establishing OSTP also sets up a top-level advisory committee, consisting of between 8 and 14 people drawn from a variety of fields, which will conduct a two-year investigation of federal science support and priorities. One of Stever's first acts was to recommend that Ramo be appointed chairman of that committee, a suggestion which Ford promptly accepted. The other members will be appointed later this month. (Ramo's appointment, incidentally, will present an interesting situation if Carter becomes President, for Ramo was a co-chairman in 1972 of a committee of scientists and engineers supporting the candidacy of Richard Nixon.)

Stever has begun to staff the office with people drawn from NSF's science policy office and a few individuals on secondment from other government agencies. In addition, he has appointed two senior policy consultants, William Nierenberg, Director of the Scripps Institution of Oceanography, and Donald Kennedy, Chairman of the Program in Human Biology at Stanford University. Both will devote half their time to OSTP, assisting in the development of policy studies on biological and environmental issues. Other consultants, Stever indicated, will be called upon as needed.

Asked last week what he considers as OSTP's chief goal, Stever said, "some scientists think that the goal should be to increase the support for science, but they are mistaken. The important thing is to establish an easy relationship at the top level of our government for the scientific community to have an input" into national policy.   **Colin Norman**

USSR

● The return of the Salyut 5 crew without having set a new endurance record has aroused speculation abroad as to whether a premature return was necessitated by the psychological stresses of the voyage. This is doubtless due to the fact that it is the first time that the Soviet press has been so explicit about the monitoring of the cosmonauts, which, it appears, involved the analysis of all routine communications with ground control to detect signs of stress.

Cosmonauts Volynov and Zhlobov wanted to be kept up-to-date with world news and sporting events as well as enjoy the on-board entertainments of taped music and a set of photographic slides. In the early part of the flight it was noted that "every detail about the progress of the Olympic Games gave them additional reserves of energy", and during the flight certain innovations were introduced—routine transmission from base were given a background of soft music and special emphasis was placed on "warmth and lively human interest in the concerns of the crew" shown by the communicators.

The official reports, however, do not suggest that the stresses developed were inadmissibly great; the new measures suggest an experiment in remote-control psychotherapy rather than a psychological emergency. Soviet space psychologists have long been concerned with the problems of in-flight sensory deprivation (including the lack of wide human contacts). Over the years this has led to a number of diverse selection procedures for would-be cosmonauts, ranging from the idea that candidates who report monochrome dreams are preferable to those who dream in colour, to the recent pronouncement that no more women will be accepted as cosmonaut-pilots, although they will still be eligible to serve aboard space-craft as "experts"—doctors, astronomers or stewardesses.

● A recent decree of the Central Committee of the Communist Party and the Council of Ministers of the USSR focused on "urgent measures for ensuring for the national economy fuel, electrical and thermal power, and the economic use of fuel and energy reserves". Addressed to all strata of society from the Councils of Ministers of the Union Republics down to the managers of individual enterprises, it called not only for all possible savings but also for the increased use of "peat, shale, briquettes and timber". It was somewhat reminiscent of a speech by Academician Vladimir A. Kirillin, Chairman of the State Committee for Science and Technology, during his visit to Britain in 1974. This extolled Soviet advances in the technology of fast breeder nuclear reactors, and also stressed that in the immediate future the Soviet power industry envisaged a considerable expansion of open-cast mining for low-grade coal.

The new emphasis on saving and on the use of low-grade fuels may be associated with recent hints of setbacks in the nuclear power plans. Writing in *Pravda,* Academician Nikolai A. Dollezhal (the chief

designer of the reactor for the first Soviet nuclear power station) indicates that there are still considerable engineering problems involved in the construction of nuclear stations, that the manpower involved in installing the equipment is some 2-3 times greater than for thermal stations, and that the efficiency of nuclear stations is generally less than that for thermal.

Moreover, he says, "there are grounds for assuming that in the not too distant future we shall be close to exhausting the 'ecological capacity' of the region of present siting of nuclear power stations." The new economy drive is aimed at ensuring the "unconditional" fulfilment of the five year plan; consequently neither industrial production nor fuel exports will be affected by the measures.

● '*Melioratsiya*', the ten-year-old land-improvement scheme involving drainage and irrigation projects and the general management of soil resources, has received a fresh emphasis. Following the disclosure of new plans over the past few months, *Pravda* has identified the scheme as "a most important task of the whole party, the whole Soviet nation".

This latest move to boost agricultural production includes the resurrection of far-reaching plans to divert northward flowing Siberian rivers south into central Asia and Kazakhstan. In the shorter term, the new measures include calls for substantial increases in the yields of cereal and other crops from "improved lands".

The renewed importance accorded to *melioratsiya* places involved workers high in the industrial hierarchy: incentives range from a special "feast day" for all concerned, to the title "Master of Irrigation" (First or Second Class) for outstanding individual contributions.

During the recent *Biosfera-76* exhibition in Minsk it was revealed more than 2 million hectares of marshland have already been drained in the Byelorussian SSR; and the past five years have seen an increase in the crop-yield of the reclaimed lands. Nevertheless, erosion is causing losses of up to 20% in crop production, and it is now proposed that some 75% of the peaty soils should be put under grass, leaving only 25% for cereal crops. With the continuing loss of productive soil to industry, and the extensive pollution of water resources also causing serious concern, the indications are that the new plans for *melioratsiya* will require considerable efforts if targets are to be met.

● The Soviet Union has agreed to cease whaling within the next two years, according to a recent statement attributed to Mr Nikolai Makarov, Chargé d'Affaires at the Soviet Embassy in Ottawa. This is a reversal of a long-standing Soviet policy, which maintained that a whaling moratorium would be positively harmful, since it would put an end to research on the biology of whales.

According to a spokesman of the USSR Ministry of Fisheries shortly before the 1974 Session of the International Whaling Commission, the established seasonal quota is insignificant, and there is "no biological necessity" to stop whaling completely since the USSR (which, together with Japan, takes 90% of the world's catch) "consistently and accurately observes all the provisions of the Whaling Convention, while attaching specially great importance to the development and implementation of effective measures to protect the whales".

At the 1976 session in June, the Soviet Union strenuously opposed the proposal to set quotas by "yield by weight", rather than by the "maximum sustainable yield" introduced in 1961. The USSR disapproved of the change, to be applied in the first instance to sperm whales only, arguing that the Commission had already done much in the past two years to maintain sperm whale stocks.

The reversal of policy is more than a cause for satisfaction among conservationists; hitherto, it is said, sperm whale oil has played an important role in the manufacture of Soviet tanks and missiles.   **Vera Rich**

IN BRIEF

Williams the DES

IN a Cabinet reshuffle Shirley Williams last week took over the post of UK Secretary of State for Education and Science from Fred Mulley. While Mr. Mulley's low-profile tenure of the post —marked by a period of economic stringency, cuts and out-of-work teachers—led to little in the way of long-term science policy, hopes are high among scientists and policymakers that Mrs. Williams will provide a different style of leadership, taking science under her own wing (rather than leaving it to a junior Minister) and generally infusing some optimism into what is at present a gloomy scene.

Mrs. Williams was a junior Minister for Education and Science between 1967 and 1969; she returns to the Department from her position as Secretary of State for Prices and Consumer Protection, held for the past two years.

More for US research

Government spending on science and technology in the United States is expected to reach $23,500 million during the fiscal year beginning October 1, according to figures recently published by the National Science Foundation (NSF). That would represent a modest increase from this year's level of support, even when inflation is taken into account.

The welcome increase follows a long period of decline in the federal science budget, as inflation has gradually eroded its purchasing power. The increase will be sufficient only to restore science support to its 1972 level, however, which in turn was 20% below that of 1967, the peak year of federal science support. The growth next year is almost solely attributable to large increases in funding for energy and defence research and development.

New orchid for Britain

Whatever its effects on wildlife in general, this year's warm dry spring brought a notable addition to the British flora: the orchid *Ophrys bertolonii*. A single specimen has been found near Swanage, Dorset, growing in undisturbed downland turf; how it got there will remain a mystery, unless some enthusiast confesses to having planted it there as a seedling some years ago. One of the loveliest and most unmistakable of European orchids *O. bertolonii* is essentially a plant of the western Mediterranean, although it occurs north of the Appenines and is also recorded from Bulgaria.

The notion that the British specimen has been in position for some years without flowering is strengthened by the discovery in Gloucestershire, also this season, of a second species, *O. sphegodes*.

IT must have come as a surprise to most people in Britain to learn that, according to the statistics for food consumption recently published by the UK Ministry of Agriculture, Fisheries and Food (MAFF), the nation's population is on average eating less than the minimum diet recommended by the United Nation's Food and Agriculture Organisation (FAO). Britons are apparently saved from starvation only by the efforts of the confectionery and brewing industries, whose products contain sugar that makes up for what would otherwise be a significant deficiency in calories.

It is difficult to take these figures seriously. If the average level of consumption is so near the starvation line, then something like half of the UK's population should show symptons of undernourishment, for the least-privileged members of society probably eat fewest sweets and drink least beer. Yet it is rare to see anyone except a criminally neglected child or an uncared-for elderly recluse, who is seriously underweight. One cannot walk along a city street in Britain without seeing many who are grossly overweight: The school medical service complains about the increase in the number of obese childen. Surveys show that as many as 75% of middle-class and middle-aged women, and over 50% of men, worry because they are overweight. Food advertisements push products that are low, not high, in calories. Newspapers are full of diets devised to allow consumers to lose weight without suffering the pangs of hunger. As a nation Britain shows all the signs of overeating, not of consuming

too little. The MAFF not only suggest that Britons eat too little food of any kind, but also that "the quality of food consumed shows a steady decline". This view is based mainly on data showing falls in the consumption of meat and other animal products, and of sugar. But as Dr. J. V. Durnin,

MAFF gaff

KENNETH MELLANBY

---

a nutritionist at Glasgow University, has commented in *The Times* newspaper, these changes should be viewed as a limited improvement, and not a deterioration in feeding habits. Moreover, they accord with a recommendation from the Royal College of Physicians.

The MAFF seems intent on perpetuating the fallacy that, because some protein is necessary for health, the consumption of more animal

products leads to better nourishment. Some time ago, the Minister even suggested that any reduction in the amount of meat eaten in Britain would give rise to serious malnutrition. Britain's diet may indeed be changing. Rising costs may be preventing everyone from consuming all the things they might wish to eat. Some people may be getting less pleasure from eating, or, more likely, from overeating. But in presenting dietary data, the MAFF should surely pay heed to the principles of nutrition, rather than to those of hedonism.

Those living in Britain can observe the real situation, but what will observers in other countries, or in organisations like the FAO, make of the MAFF statistics? Will the UK's 55 million citizens be added to the thousands of millions in countries even poorer than Britain already listed as suffering from food shortages? In the past, many statistics published by international bodies have exaggerated world starvation and malnutrition. It is revealing to find that equally exaggerated data can be produced for a country like Britain, where accurate information might be expected.

Yet there are too many hungry and even starving people in the world today. There are many countries where overeating is not, as it is in Britain, the main cause of 'malnutrition'. The problem can only be solved if there are accurate statistics for food consumption, and proper estimates of food requirements, for all countries. A start should be made by producing such information for Britain.

Ball lightning

SIR,—Ball lightning is a relatively rare phenomenon, usually occurring under conditions of very strong electrical fields and usually associated with storms, though not necessarily in the storm area. The balls can be from one inch to several feet in diameter and can have various colours. Some explode violently and some fizzle out quietly. The balls move through the air, apparently independent of wind and gravity, and are known to enter structures—even through a metal window screen and into a metal aircraft. There is no good theory to explain ball lightning, but J. R. Powell and D. Finkelstein are working on a d.c. field theory in which a strong electric field adds energy to the ball to sustain it (*Structure of Ball Lightning*, Brookhaven National Laboratory, Upton, New York).

Little is known about the ignition hazard of ball lightning, but in the course of investigating accidents in the past ten years, we have heard the following statements from witnesses:
● Distillate was being loaded into the open top of an 8,000 gallon transport truck. "A ball of light travelled along the fill pipe and down the droptube. It entered the truck compartment and the truck blew up."
● Solvent was being loaded through closed piping into the bottom of a 7,600 gallon transport truck. "A ball of light followed along the fill pipe toward the truck and disappeared. Then the truck blew up."
● An observer on a ship several miles from an empty VLCC (very large crude carrier) tanker. "A ball of light travelled along the deck of the ship and disappeared. Then the ship blew up."
● Jet fuel was being loaded into the open top of a transport truck. "A ball of light entered the truck compartment and it blew up."
● A retired New York City fireboat captain, Charles Wilson of Codan Marine Inc., New York. "I know of three cases where a ball of light was reported to have moved across the deck of a barge just before the barge blew up."
● A tanker captain with the same corporation, Captain Wykoff, reportedly "saw a ball of light move across the deck toward a compartment before it blew up."
Taken individually, these are each incredible and are usually ignored by safety experts. Since there are these eight cases reported by separate observers, it appears that ball lightning might be an infrequent and unrecognised source of ignition.

There probably are other incidents, and we are soliciting any information that others may have. Our concern is that this is an unrecognised source of ignition in fuel transport operations and that conventional protective methods may be inadequate.

Forecasting error

SIR,—Kenneth Mellanby, in a short but cogent article ("Forecasting Error", August 5, page 441), is highly critical of the state of the art of forecasting many of the social and economic components of present society.

Most of his strictures are only too true. I would however take issue with his implication that "only some form of rigid totalitarianism could improve the statistics". This can surely be tested by examining the forecasting skills of societies which have for some time displayed this characteristic. To my knowledge there is no evidence that they do have a greater predictive success rate; in fact the impression is quite the reverse.

To improve data sources used in predictions would involve the public as individuals and groups in providing information on present and intended actions and aspirations which, for various reasons, they are unwilling to divulge with any degree of spontaneity. At least part of this unwillingness stems from a sense of isolation from the decision-taking which would (hopefully) be based on the information. If truly participatory decision-taking processes existed, after a due period of time to allow for cultural inertia, the inclination to provide adequate information from which to derive alternative policy plans might well emerge.

Better data require more democracy, not less.

DAVID R. COPE
Institute of Planning Studies, University of Nottingham, UK

Mistaken parameter

SIR,—Politicians and others have been criticised in the national press for the misuse of the word "parameters", but I have yet to see similar charges levelled against scientists who have much less excuse for this practice. During the past three years the tendency to describe components, factors, attributes and so on as parameters has become frequent in most scientific journals, covering agricultural research and related fields, published in the UK and abroad.

To anyone in the habit of using parameters with gay abandon I would recommend the definition given by Professor D. J. Finney in *An Introduction to Statistical Science in Agriculture*:

"Numerical values that serve . . . to identify a particular distribution curve, as a member of a whole family, are termed *parameters* . . ."

I would predict that if the term were restricted to numerical values, without any greater precision of meaning, the frequency with which it is used would be halved.

I. G. MONTGOMERIE

Mycology Section, Scottish Horticultural Research Institute, Dundee, UK

Electrifying demonstration

SIR,—The theoretical approach by Marble, MacVicar and Roberts (Correspondence, July 15, page 171) is not necessary. For many years, when teaching electrostatics to first year students, I used to stand on a 5 cm thick block of paraffin wax and charge myself up from a small Van de Graaf generator capable of giving 300,000 volts on open circuit. This made my hair stand on end in a convincing manner, and the sparks which I could get from a hand-held object to earth would certainly have ignited any explosive gas mixture.

Without wishing to compete with the above authors in numbers of significant figures, I must have reached between 100,000 to 200,000 volts with respect to Earth without harm—incidentally illustrating for the sake of the students the old GEC adage: "It's the amps, not the volts, wot kills yer".

news and views

Eukaryotic mRNA : trouble at the 5'-end

from Beverly Griffin

UNTIL recently, the story of the 5'-termini of eukaryotic messenger RNAs seemed consistent and scientifically coherent. The evidence emerging seemed to confirm two separate conclusions. First, eukaryotic messenger RNAs contain 7-methylguanosine triphosphate, $m^7G(5')ppp(5')X$, at their 5'-ends. To use the terminology introduced by Rottman *et al.*, they are "capped".

This seemed to hold true for mRNAs from a large number of cells: mouse myeloma cells[2] and L cells[3,4], HeLa cells[5-7], Novikoff hepatoma cells[8], Erhlich ascites carcinoma cells[9], brine shrimp (*Artemisia salina*) cells[10] and silk fibroin (*Bombyx mori*) cells[11].

The same 5'-terminal ends were found for mRNAs from both DNA and RNA viruses, such as: reovirus[12], Newcastle disease virus[13], vaccinia virus[14,15], Sindbis virus[16,17]; avian sarcoma (ASV) virus[18,19], vesicular stomatitis virus[20,23], adenovirus[24], and cytoplasmic polyhedrosis virus[25]. They were also found in several plant viruses: tobacco mosaic (TMV) virus[26,27], alfalfa mosaic virus[28], and brome mosaic virus[29].

Translation requirement

Second, the presence of the 5'-terminal 7-methylguanosine (that is, the "cap") is required for translation. Two separate, but related, studies using mRNAs from reovirus or VSV showed that the removal of the cap resulted in a loss of translational activity in *in vitro* protein synthesising systems[30,31].

Following on these findings, other results on the how and when and where began to emerge. Aurin tricarboxylic acid (ATA) which inhibits translation, was found by Both *et al.*[31] also to inhibit messenger RNA methylation, leading them to suggest that the cap structure is important in messenger-ribosome complex formation, the absence of 7-methylguanosine markedly reducing formation of the complex. Rose[22] showed that messenger RNAs with 5'-triphosphate ends, but no 7-methylguanosine, were present in VSV but were not found on ribosomes;

he therefore postulated that capping might have a role in ribosome recognition of mRNA. Further corroboration and refinement came from the results of Roman *et al.*[32], who, studying mRNA binding in a fractionated wheat germ system, obtained results which suggested that the capped mRNA was essential for the interaction of the 40S ribosomal subunit with the 60S subunit to give the 80S ribosomal complex; in competitive inhibition studies, 7-methylguanosine-5' phosphate was found to have no effect on the formation of the 40S complex, but to inhibit the transition of the 40S ribosome-met-tRNA$_f^{Met}$ complex to the 80S ribosome complex. Similar experiments were carried out in other laboratories and similar results obtained[33-35]. In some interesting studies with model compounds, Both *et al.*[35] found that the presence of 7-methylguanosine triphosphate at the 5'-end of some ribopolymers was not in itself sufficient to ensure ribosomal binding. For example, capped polyriboadenylic acid did not bind to any significant extent, whereas capped polyribouridylic acid could form 40S complexes, and capped ribopolymers containing both A and U could form 80S complexes. Their results strongly implicated not only the 7-methylguanosine in ribosome binding, but also pointed to the need for sequences rich in A and U for stable binding. It does seem important to note here that some ribopolymers such as $(A,U)_n$ bound stably to ribosomes (even though they did not contain a 7-methylguanosine cap). The dependence on the presence of adenosines and uridines for stable complex formation between eukaryotic mRNA and ribosomes makes the sequence of brome mosaic viral RNA fragment protected by eukaryotic ribosomes all the more interesting; Dasgupta *et al.*[29] found the sequence which precedes the translation start signal in this message to be $m^7G(5')-ppp(5')GUAUUAAUA$ . . . , a sequence notably rich in A and U.

For a further probe into the role of capped mRNAs in protein synthesis, Shafritz *et al.*[36] studied the interaction

of mRNAs from VSV, EMC, and histone mRNA with purified initiation factors. They demonstrated complex formation between mRNAs and factors IF-MP, IF-M3, and IF-M2A (but none with IF-M2B). For inhibition studies, they used excess 7-methylguanosine triphosphate, and in only one case, that with IF-M3, was this nucleotide able to inhibit messenger-factor complex formation. Their conclusion from their studies was that initiation factor IF-M3 might be essential for the binding of certain mRNAs to ribosomes.

Exceptions

So far, so good. And now the trouble starts, and we come to the findings that begin to question the validity of the above observations as generalisations to all eukaryotic mRNAs. Two papers which appeared simultaneously say that polio viral mRNA is not capped by its 5'-terminal's being pUp[37,38]. Moreover, encephalomyocarditis (EMC) virus mRNA appears to contain no capped 5'-end[39], nor do the mRNAs from the plant virus, satellite tobacco necrosis (STNV) virus[33,40]. So not all eukaryotic mRNAs are capped.

Moreover, a paper has now appeared which says that translation does not require 7-methylguanosine; Rose and Lodish[41] were able to translate mRNAs of VSV in an *in vitro* system even after the terminal 7-methylguanosine had been removed. Thus, translation of some messengers in some protein synthesising systems may not require the terminal cap.

To add further to the uncertainties, Filipowicz *et al.*[42] find a cap-binding protein in extracts of brine shrimp embryos, but this protein which binds to mRNAs and is postulated to promote binding to ribosomes, is not IF-M3, nor indeed does it appear to be any of the other protein initiation factors.

It is clear from the paradoxes mentioned above, that different as well as better-defined experiments need to be carried out in order to reach definite conclusions about the structure and

function(s) of the 5'-end of eukaryotic mRNAs. With few exceptions, most of the studies to date have been so similar in kind that if a trap is there, it would have captured in turn almost every investigator. For example, most studies on mRNA have been carried out on species purified *via* the polyadenylated 3'-ends of the RNAs. But not all mRNAs contain poly(A), and who can yet say that poly(A) may not be added merely to "store" mRNAs until they are needed, and then removed to produce "fuctioning" messages? (Marbaix *et al.*,[43] point to the role of poly(A) 3'-terminal sequences as one of stabilising eukaryotic mRNAs.) Moreover, most studies on the function of the cap at the 5'-end of mRNAs have used mixtures of messenger RNAs and the wheat germ *in vitro* translating system. (There are a few exceptions to this criticism. For example, see Yang *et al.*[11] and Shafritz *et al.*[36] for use of the rabbit reticulocyte cell-free protein synthesising system.) Even after considering the exceptions, it is not clear whether one is justified in drawing firm conclusions about mRNAs from a single protein synthesising system. It seems from the data accumulated so far that studies on mRNAs may merely reflect the idiosyncracies of the individual *in vitro* translation systems. Moreover, with the mRNAs that fail to be translated, no real proof exists that the chemical procedures used to remove the capped ends have not damaged the RNAs in other ways. Rose and Lodish[41] say : "We initially had great difficulty recovering translatable VSV mRNA after periodate-oxidation and β-elimination, and clearly did not completely overcome the problem of degradation. Thus, we suggest that similar studies indicating a requirement for 7-methylguanosine in translation of cellular mRNAs should be more carefully controlled for possible non-specific effects of the chemical procedure".

If 7-methylguanosine survives as a requirement for translation for most mRNAs and in most protein synthesising systems (as well as in the cell?), it will be interesting to see whether mRNAs for which no cap has been found, such as those from poliovirus or EMC, have a 7-methylguanosine (as a modified base) anywhere near their 5'-termini.

More about the 5'-end

What else do we know about the 5'-ends of eukaryotic mRNAs? Most eukaryotic mRNAs, in addition to containing 7-methylguanosine triphosphate at their 5'-ends, also appear to contain 2'-O-methylated bases as the first, and frequently the second, nucleoside following the capped end. Some exceptions to this have been found, notably among the viral mRNAs. (For ex-

Salt on roadside verges

from Peter D. Moore

THE impact of disturbance upon the flora of roadside verges is a subject of considerable interest to conservationists and to environmental planners, for the habitat occupies a large area of our country and provides an opportunity for combining utility with aesthetic and scientific interests. In the main, interest has centred upon such effects as lead pollution from motor exhausts, but an additional stress imposed on these verges is provided by the salt which is applied to roads in winter.

The problem was recognised and discussed by Westing (*Phytopathology*, **59**, 1174; 1969) in America where, at the time of his survey, some 6 x 10[6] tons of salt were applied to the highways of the northern states during the winter. This figure was increasing by about a million tons every year. In the United States, applications of 6 kg m^{-1} along the side of the road are frequent. In Britain, Davison (*J. appl. Ecol.*, **8**, 555; 1971) estimated that applications of 3 to 4 kg m^{-2} were experienced by the roadside verges of Northumberland.

The presence of salt in the soil lowers the water potential and influences soil structure, which may make water less available and reduce aeration for the resident plants. The effects on trees have caused concern in the United States, where Westing (*Econ. Bot.*, **20**, 196; 1966) has described a decrease in the population of the sugar maple (*Acer saccharum*) caused by a combination of drought and salt applications. Low rainfall in

summer, of course, can result in reduced leaching and the persistence of salt applied during the winter.

In Britain, trees are not permitted to grow close to the edge of roads, so are not subjected to the greatest stress; this is felt instead by the characteristic grasses and herbs. Analysis of verge soils by Davison (*op. cit.*) showed that sodium levels in April could be ten times those in unaffected grassland, but usually fell to normal by September. Sodium concentrations in plant leaves were often five to ten times the normal level.

It may be expected that the continued application of salt to roadsides would result in the selection of more tolerant species and this has now been observed by Matthews and Davison (*Watsonia*, **11**, 146; 1976) in areas around Newcastle-upon-Tyne, Northumberland. In a survey of changes in roadside flora they describe reduced species diversity and the selection of resistant species. They also describe an invasion of maritime species, such as *Aster tripolium, Puccinellia maritima, Plantago maritima* and *Sueda maritima* up to 13 km from the sea. These halophytic species have been particularly effective in the colonisation of new (less than 3-yr old) roads. It is likely that these species have been brought in as seeds on the wheels of vehicles. It will be interesting to see whether the development of a saline roadside flora continues along our highways in a similar manner to the establishment of a railway flora in the last century.

ample, see the references to Newcastle disease virus, Sindbis virus and TMV virus mRNAs.) Structures of the type m[7]G(5')ppp(5')X^{m}pYp are now being called cap I structures and those of the type m[7]G(5')ppp(5')X^{m}Y^{m}pZp are being called cap II structures[44]. Perry and Kelley have carried out a very interesting study on the kinetics of methylation of the 5'-ends of mRNAs. Their results suggest that the 5'-terminal cap I structures of mRNAs are derived from capped heterogeneous nuclear RNA and are conserved during processing. Cap II structures, on the other hand, are not found in the cell nucleus, but arise by a secondary methylation after the mRNAs have entered the cytoplasm. This secondary methylation appears to be restricted to a particular subclass of mRNAs which have a high frequency of pyrimidine nucleosides at position Y (see above), and are among the more stable

mRNAs. Studying mRNA from cytoplasmic polyhedrosis virus, Shimotohno and Miura[45] have shown that methylation at the messenger 5'-end occurs first at the 7-position of guanosine, and only after chain elongation has proceeded for a few nucleotides is the 2'-position of the first base which follows the cap structure (adenine, in this case) methylated.

(The discovery in cell extracts of enzymes which cleave at the 5' terminal and remove the cap will no doubt help resolve some of the problems and conflicts now being encountered in studies on eukaryotic mRNAs. Three papers have appeared which report on the presence of such an enzyme activity in HeLa cells[7], in extracts from brine shrimp[46], and in cultured tobacco cells[47].

One of the early papers in this field, and probably the one which was most influential in bringing the capped ends

of mRNAs to the attention of the scientific public was the paper by Rottman, Shatkin and Perry[1] entitled "Sequences Containing Methylated Nucleotides at the 5' Termini of Messenger RNAs: Possible Implications for Processing". In one of the most important papers to appear and challenge the ideas widely quoted (and therefore beginning to be accepted as dogma) on the function of the cap in eukaryotic mRNAs, Rose and Lodish[41] say that their (conflicting) results "suggest that methylation is involved in synthesis or processing of (VSV) mRNAs into the correct poly(A)-containing mRNA species". And so, have we gone through so much only to come full circle?

I should like to conclude by making a few remarks. First, 7-methylguanosine is an extremely interesting molecule. One of the early papers on capped structures referred to the cap as a "bizarre" structure[2]. The better word might be "versatile". Haines *et al.*[48] found 7-methylguanosine to have a potentiometrically determined pK_a of 7.0. This means that at pH 7.0, it exists as an equilibrium between two ionic forms:
Lower the pH, and form (1) becomes more important. Raise the pH, and form (2) becomes more important. The implications of this are that the capped structure would be expected to be remarkably sensitive to localised pH changes within the cell.

In an unusually interesting paper in a too-neglected field, Seeman *et al.*[49] have studied sequence specific recognition of nucleic acids by proteins. For double-helical RNA (or DNA), their analyses lead them to conclude that whereas single hydrogen bonding interactions were inadequate to explain the specific protein-nucleic acid complexes they observed in model studies, pairs of hydrogen bonding interactions might play a role in protein-nucleic acid recognition. To return to the capped structure, within this structure (even ignoring any effects due to phospshate groups) would appear to be the requisite qualifications for specific interactions with proteins; cursory examination would suggest a possible stable interaction with, for example, the guanidinium group of an arginine molecule. With a slight change in pH, the tautomeric form of 7-methylguanosine could change and the complex be thereby strengthened, or weakened, depending on the nature of the change. The word versatile reflects the potential of the capped structure to respond in a very sensitive way to its environment; its environment in turn can confer on it the properties for self-regulation, whether in messenger binding or processing or transport.

The questions raised by the presence (or absence) of the cap at the 5'-ends of eukaryotic mRNAs have clearly stimulated considerable interest, and even that form of excitement which is so important to scientific research. But the tale is unfinished. And so, the reader is left with the opportunity to carry on with the story . . . .

Why do stars twinkle?

from B. J. Uscinski

ALTHOUGH the twinkling of stars is apparently a simple phenomenon, the theory which has been developed to explain it is anything but simple. The article by Jakeman, Pike and Pusey on page 215 of this issue of *Nature*, shows that it is now possible to test the validity of the new multiple-scatter theory which has evolved over the past 10 years. This is an important step forward, since the theory is essential not only for the study of optical scintillation, but also in investigating the scintillation of quasars and pulsars caused by the interplanetary and interstellar media respectively. Up till now it has not been possible to make satisfactory experimental tests of the new body of multiple-scatter theory since detection and recording techniques have not been sensitive enough.

The early 1960s saw the beginning of serious efforts to study the propagation of waves in media containing random irregularities of refractive index. One of the first attempts to deal with the case when the intensity fluctuations of the wave become large was the so called 'Method of Smooth Perturbations'. (Obukhov, *Izv. Akad. Nauk SSSR, ser. geofiz.*, No. 2, 155; 1953). This method became widely known, having appeared in a book by Tatarsky (*Wave Propagation in a Turbulent Medium* (trans. by R. A. Silverman), McGraw-Hill, New York, 1961), but it was soon realised that it was not valid for the case of multiple scatter (Barabanenkov *et al.*, *Usp. fiz. Nauk*, 102, 1; 1970). Subsequent methods based on repeated application of the Born approximation were able to deal adequately with the multiple-scattering of waves in media where the perturbation caused by a single irregularity is small (Shishov, *Izv. Vyssh. Ucheb. Zaved. Radiofizika*, 11, 866; 1968; Tatarsky, *Zh. Eksp. Teor. Fiz.*, 56, 2106; 1969; Beran and Ho, *J. opt. Soc. Am.*, 59, 1134; 1969). This came to be known as the Markov approximation, and such media as "weakly irregular" media.

The new theory is based upon a set of partial differential equations for the various moments of the field, and theoreticians generally agree that they are valid in the case of multiple scatter (Barabanenkov, *op. cit.*). The equations have several interesting features. First, the variables can be scaled in such a way that each equation contains only one parameter, which is the same for all the equations (Barabanenkov, *op. cit.*). Hence all weakly irregular media can be classified as regards their scattering properties in terms of a single parameter. Second, the level of intensity fluctuations, sometimes called the "scintillation index"

or the "normalised contrast", found by solving the equation for the fourth moment exhibits peaks or foci where values well in excess of unity occur in certain conditions (Dagkesamanskaya and Shishov, *Izv. Vyssh. Ucheb. Zaved. Radiofizika*, **13**, 16; 1970; Shishov, *Zh. Eksp. Teor. Fiz.*, **61**, 1399; 1971). Finally, a marked reduction in the scintillation index or normalised contrast is predicted when the signal is received over a wide frequency band.

It is indeed interesting that Jakeman *et al.* have been able to observe these last two effects. As the authors point out, earlier failures to observe the predicted effects have probably been due to instrumental insensitivity and averaging of the response. They do not necessarily indicate that the theory is wrong. The new detection techniques can now be put to an obvious and necessary use. Multiple scatter theory can be tested experimentally. This is essential since the theory is widely used as the basis for investigating stellar objects, as well as various aspects of both the interstellar and interplanetary media. It is also used when probing the atmosphere with laser beams.

The tests would have to be carried out in controlled conditions in a laboratory. As Jakeman *et al.* remark, some of the effects to be measured are heavily dependent on the model. If naturally-occurring irregular media are used it is difficult to measure the autocorrelation function and scale size of the irregularities. Moreover, there could well be a mixture of scale sizes present, and the statistics of the medium could be non-stationary. A stationary irregular medium with a single scale size and an autocorrelation function which can be determined could be synthesised in the laboratory from irregular plastic layers for example. In these conditions the new detection techniques would allow the predictions of multiple-scatter theory to be systematically verified, especially the focusing effect and the classification of media in terms of the single parameter.

In addition, the probability distribution of the wavefield could be determined for different scattering regimes. It has sometimes been asserted, with little theoretical justification and no qualification, that the logarithm of the amplitude is normally distributed. There seems to be more reason to suspect that the probability distribution is different for different regimes, and while being similar to a log-normal distribution in some circumstances is more like a Gaussian in others (Barabenkov, *op. cit.*).

Until controlled tests of this type are carried out, multiple-scattering theory will remain open to doubt and criticism. □

New limits on variability of fundamental physical quantities

from Paul Davies

ONE of the greatest mysteries of nature is why the various dimensionless ratios of fundamental physical quantities take the apparently arbitrary values that we find for them. Why, for example, should the proton mass M_p be 1836.1 times greater than the electron mass M_e and not some other, equally meaningless, number? Or why should the square of universal electronic charge, e^2, be 1/137.036 times the product of Planck's constant $\hbar$ and the speed of light c? If any old numbers will do, why not something elegant, like 1 or π?

Three schools of thought have arisen about these ratios. One supposes that the numbers are not arbitrary at all, but will emerge as a precise result from a future theory of matter, in the same way that the anomalous magnetic moment of the electron (0.00116 times the "normal" magnetic moment) may now be derived from quantum electrodynamics. The second does not attempt to explain these numbers, but points out that if they were very different from their observed values, it may not be possible for them to be observed—because the existence of living organisms (to do the observing) depends on many complicated processes more or less sensitive to these values.

The final school of thought is a more radical one, proposing that the numbers actually observed are indeed nothing special, because those numbers are not in fact constant, but are changing with time. Thus, the values 1836.1 or 137.036 for example, are just the 1976 values, and have no fundamental significance.

The reasoning which led to this idea arose in the 1930s from a study of cosmology. Several physicists and astronomers, most notably P. A. M. Dirac and A. S. Eddington, drew attention to the very large dimensionless ratio which one obtains by expressing the age of the universe in atomic units of some sort. This number is about 10^{40}. By apparent coincidence, 10^{40} is roughly the same ratio by which electric forces are stronger than gravitational forces between two atomic particles. Dirac argued that any fundamental theory of matter would be unlikely to throw up a number so preposterously large as 10^{40} so that perhaps the latter ratio is actually determined by the former, that is that there is a causal connection between these two large numbers. If that is so, then as the Universe grows older, and the first ratio increases, so must the force of gravity dwindle in relation to electromagnet-

ism. This could come about by a decrease of Newton's gravitational "constant" G, for example, or by an increase of the electronic charge e.

Fortunately, it is possible to provide observational checks on the hypothesis that some of these ratios may be time-dependent. This is because modern technology enables us to study matter in regions of the Universe which are so distant that the light from them has taken several billions of years to reach us. Therefore, we see those regions as they were when the Universe was only a fraction of its present age. Any variation in the numerical ratios which is based on a cosmological cause might therefore be expected to show up in the spectra from distant galaxies or quasars. The redshift of the spectral lines fixes the distance, and hence the age of the source according to Hubble's law of the expansion of the Universe. But if it is also possible to measure the fine structure of the spectral lines (a small splitting due to relativistic effects in atoms) then a value for the fine structure constant $\alpha = e^2/\hbar c$ may be determined. In 1967 Bahcall and Schmidt were able to fix, using this technique, the possible variation in α to be below about one part in 10^{12} per year, thus ruling out the theory that G is fixed and e^2 increases in proportion to the age of the Universe (about 1 part in 10^{10} per year).

Recently, not only fine structure, but hydrogen hyperfine structure has been detected in a very distant radio source. This hyperfine structure is an electromagnetic effect which depends on the small coupling between the proton and electron in the hydrogen atom, and its measurement yields a value for the ratio $\alpha^2 M_e/M_p$. In a recent issue of *Physical Review Letters*, three American astronomers, A. M. Wolfe, R. L. Brown and M. S. Roberts use the new observation of hydrogen hyperfine absorption to fix the variation of $\alpha^2 M_e/M_p$ to as little as two parts in 10^{14} over at least 35% of the age of the Universe (the "look-back" time of the source). They also confirm Bahcall and Schmidt's result by observing fine-structure in the magnesium spectrum from this source. These results taken together (and assuming the internal structure of the proton does not change) completely rule out any small power variation of α or M_e/M_p over cosmic time scales. Of course, Dirac's theory can only be ruled out by simultaneously providing a restriction on the variation of G, a much more

difficult task.

Although this is a negative result, the importance for theoretical physics of keeping the natural constants constant makes these occasional cosmological checks well worthwhile. In the absence of a theory of natural constants, the significance of their numerology will have to be left to the philosophers to ponder.

Herpes virus induction of F$_c$ receptors

from R. S. Kerbel

WHEN cells are infected with viruses or are transformed by oncogenic viruses, alterations in plasma membrane components often occur. The characteristics of these surface changes and how they may relate to the biological behaviour of the cells have been popular areas of study for both virologists and immunologists alike.

One example of how spectacular these changes can be concerns induction of surface receptors, specifically F$_c$ receptors. Over 12 years ago, Watkins noted that cultured HeLa cells were able to absorb antibody-coated erythrocytes and form rosettes after the cells were infected with herpes simplex type 1 virus (*Nature*, **202**, 1364; 1964). This was later confirmed by Yasuda and Milgrom who used various different cell lines derived from both man and monkey (*Int. Arch. Allergy*, **33**, 151; 1968).

We now know that a variety of cells, mostly lymphoreticular in nature, have surface receptors for the F$_c$ portion of IgG immunoglobulin molecules (F$_c$ receptors). These receptors can be detected by erythrocyte–antibody (EA) rosette formation. Thus, it seems that infection with herpes simplex virus (HSV) results in induction of F$_c$ receptors, a conclusion substantiated by Yasuda and Milgrom who showed that virus-infected cells could not absorb erythrocyte coated with F(ab')$_2$ antibody fragments, but only with the fully intact antibody molecules.

The gene which codes for the receptor seems to be virally coded, and not a repressed host gene switched on by viral infection (Westmoreland and Watkins, *J. gen. Virol.*, **24**, 167; 1974). Subsequent studies have shown that mammalian cells such as hamster embryo fibroblasts oncogenically transformed by inactivated HSV types 1 and 2 can also display F$_c$ receptors (Westmoreland, Watkins and Rapp, *J. gen. Virol.*, **25**, 167; 1974).

It was only natural to ask whether other members of the herpes family of viruses could also induce the appear-

ance of F$_c$ receptors in infected cells and an affirmative answer was recently provided by Furukawa *et al.* who found human fibroblasts displayed F$_c$ receptors after infection with human cytomegalovirus (*J. clin. Microbiol.*, **2**, 332; 1975), an observation also made by Rahman *et al.* (*J. Immun.*, **117**, 253; 1976), Keller *et al.* (*J. Immun.*, **116**, 772; 1976) and Westmoreland, Jeor and Rapp (*J. Immun.*, **116**, 1566; 1976).

Now that every type of cell thus far tested from over six different species has been shown to develop F$_c$ receptor sites after infection by at least two different herpes viruses, the possibility looms larger than ever that these receptors have a role in the natural history of herpes virus infections. It has been suggested by Westmoreland and Watkins and also by Costa and Rabson (*Lancet*, **i**, 77; 1975) that the development of F$_c$ receptor sites may play a part in conferring a biological advantage on the virus and therefore in maintaining the latent nature of herpes infections, since the coating of infected cells with IgG molecules or immune complexes by the F$_c$ region of the immunoglobulin molecules might protect the cells from the destructive effects of potentially cytotoxic antibodies and lymphocytes.

Lehner, Wilton and Shillitoe (*Lancet*, **ii**, 60; 1975) suggested an alternative way in which F$_c$ receptors may be involved in the latent and recurrent nature of HSV infections, namely "double" binding of anti-HSV IgG antibodies to virus-infected cells to induced F$_c$ receptors and HSV surface antigens, by way of their F$_c$ and F$_{ab}$ portions, respectively. The F$_c$ portion of the anti-HSV antibodies would then be unavailable for either complement binding or for F$_c$ receptors on effector cells capable of mediating antibody-dependent cell-mediated cytotoxicity. Lehner *et al.* also speculate that the spread of putative HSV-induced squamous cell carcinomas might also be facilitated by double-binding of F$_c$ receptors and HSV antigens by IgG antibodies on the surface of dividing carcinoma cells. If there is indeed a relationship between HSV and squamous cell carcinoma, it will be of interest to see whether F$_c$ receptors can somehow be exploited as a tumour cell marker in this particular case.

The *in vivo* significance of induced F$_c$ receptors on herpes virus-infected cells awaits further experimentation. For the moment, the emphasis is on the various practical *in vitro* considerations of the phenomenon. A particularly illuminating example is the recent work of Rager-Zisman, Grose, and Bloom (*Nature*, **260**, 369; 1976) who found that HSV-infected target cells could be non-specifically lysed by F$_c$ receptor-positive killer cells in the

absence of specific anti-HSV antibodies; the authors provided further evidence that this phenomenon might be mediated by the cross-linking of effector cells and target cells, both displaying F$_c$ receptors, by aggregated immunoglobulins or soluble immune complexes present in the serum of the culture medium. This supports the suggestion first made by Lehner *et al.* (*op. cit.*) that complexes of HSV and IgG antibodies might bind to F$_c$ receptors of both HSV-infected target cells and effector cells resulting in killing of the target cell.

Immune complex (or aggregated Ig)-dependent cell-mediated cytotoxicity may therefore represent one of the mechanisms by which F$_c$ receptor-positive lymphocytes from normal donors can spontaneously lyse tumour target cells *in vitro*, a phenomenon observed by several investigators (for example, Pross and Jondal, *Clin. exp. Immun.*, **21**, 226; 1975; Bean *et al.*, *Cancer Res.*, **35**, 2902; 1975) and which has often been a serious technical problem in specific cell-mediated microcytotoxicity assays. If so, the use of F$_c$ receptor-negative tumour target cells or culture media free of immune complexes and/or aggregated Ig should minimise or even prevent, in some cases, spontaneous lymphocyte-mediated cytotoxicity. □

Plant–microorganism interactions

from R. M. Cooper

A symposium on cell wall biochemistry related to specificity in host–plant pathogen interactions (organised by J. Raa and B. Solheim) was held at the most northerly university in the world in Tromsö, Norway on August 2–6, 1976. The proceedings of the meeting are to be published.

THE molecular basis of the specific parasitism or symbiotic associations of certain microorganisms with a plant species, or even variety, has fascinated but eluded scientists for many years. One such specific interaction is the so-called 'gene-for-gene' relationship between biotypes of plant pathogens and their hosts 'evolved' as a result of pathogens' overcoming new resistance genes introduced by man into crops. Similarly the symbiotic association between roots of legume species and strains of the soil bacterium *Rhizobium* (a major source of biologically-fixed nitrogen) can exhibit a marked degree of specificity. These two types of specificity comprised the

main theme of this excellent symposium.

Several examples of cell–cell recognition involve interaction of surface carbohydrates or glycoproteins of one cell and a protein of the other; such as mannoproteins in sexual mating in the yeast *Hansenula wingei* (C. Ballou, University of California), O-antigen in attachment of phage to bacteria, single terminal glycosyl residues as determinants of red blood cell types and glycoproteins in aggregation of sponge cells. Recently carbohydrates from cell wall surfaces of pathogenic fungi have been implicated in specificity by their ability to induce differentially antifungal compounds—phytoalexins—in resistant and susceptible host plant cells (Keen, *Science*, **187**, 74–75; 1975). P. Albersheim's group (including A. Ayers and B. Valent, University of Colorado) reported extensively on their findings with these 'elicitors'. Initially they isolated and partly characterised them from culture filtrates of *Colletotrichum lindemuthianum* (bean pathogen) and *Phytophthora megasperma* var. *sojae* (Pms) (soybean pathogen), and subsequently found them to be an integral part of the fungal cell wall as Pms elicitor could be released from walls using a technique designed to remove surface antigens from yeast. Purified Pms elicitor induced phytoalexin accumulation in soybean, at the same rate as during infection by Pms, when applied to plant tissue in extremely low amounts (10^{-13} mol). It is a small (less than 25 glycosyl residues) predominantly β-1,3-glucan, dependent for inducing activity on terminal sugar residues. Although elicitors may have a critical role in pathogenesis they do not seem to determine specificity, since : elicitors from different races of the two fungi appear identical; response of resistant and susceptible host varieties is similar; similar elicitors to Pms are found in two saphrophytic yeasts, which suggests that plants respond to microorganisms by recognising a few common elicitors. An exciting offshoot of this work could be the development of elicitors as nontoxic fungicides.

Agrobacterium tumefaciens induces tumours in a wide range of dicots and gymnosperms but not monocots. Prerequisites for infection involve wounding of the host and attachment of virulent bacteria within 15 min of inoculation; avirulent strains are unable to attach. J. A. and B. B. Lippincott (Northwestern University, Illinois) found that the bacterial binding site resided within the polysaccharide moiety of the lipopolysaccharide (LPS) from the outer cell envelope; this fraction when isolated from virulent but not from avirulent strains inhibited tumour formation by competing with bacteria for host attachment sites,

Counting globin genes

from Pamela Hamlyn

THE molecular biology of abnormal human haemoglobins, and the study of haemoglobin variations within populations, not only provides explanations for clinically observed symptoms of diseases, but also acts as a model for the understanding of the biochemical genetics of other inherited traits. Simplicity is not one of the virtues of this particular model system. There are six main globins, α to ζ, which combine in different ways to form the various haemoglobins. The ε and ζ chains are present only in the first few weeks of foetal life.

Nucleic acid hybridisation techniques have shown that there are two genes coding for α-globin, one for β and one for δ. And now, to complete the count of the major globin genes, the number of γ-globin genes has been directly estimated (Old *et al.*, *Cell*, **8**, 13; 1976).

Two types of γ-chains are found in normal foetal haemoglobin, differing only at amino-acid position 136 which can be either alanine or glycine. The simplest interpretation of this would be that there are two structural genes for γ-globin. However, the proportions of the two types of γ-globin change after birth, and also γ-chain mutants do not occur in the ratio predicted if there are only two fully expressed genes. These observations have led to the suggestion that there are two major and two minor γ-globin genes (Huisman *et al.*, *Ann. N. Y. Acad. Sci.*, **165**, 320; 1969).

Because there are several steps between the transcription of the gene and the appearance of the protein, direct measurements of the number of genes are necessary; deductions made from the protein ratios are not sufficient. This was achieved by Old and his colleagues using a probe for γ-globin

genes. Messenger RNA from foetal red blood cells was reverse-transcribed to provide cDNA complementary to α, β and γ mRNA. Hybridisation of these cDNAs to adult blood mRNA, which contains only α and β mRNA, left the γ cDNA unhybridised and it was isolated from the hybrids. The purified γ cDNA was then hybridised to total human DNA in cDNA excess and the amount of cDNA needed to saturate the cell DNA was measured. The hybridisation of β-globin cDNA to total cell DNA was used as a comparison since it is known that there is one β-globin gene. The results confirmed that the number of copies of the β-gene was one, and showed that there were two genes for γ-globin. The different ratios between the two γ-globins which occur during development must therefore be due to differential gene transcription, or mRNA translation, rather than to gene dosage.

The method used in this study to determine gene number relies on the measurement of the rate and final extent of hybridisation with the probe in excess. This has a greater accuracy than the previously used method (Ottolenghi *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 2294; 1975) which relied on the measurement of the $C_0t_{\frac{1}{2}}$ when cDNA was hybridised back to excess total DNA. This is because with the saturation method a doubling in the gene number results in a doubling of the final plateau value, whereas in the other method the estimate of gene number depends on a small difference in the $C_0t_{\frac{1}{2}}$ normally measured on a logarithmic scale. Using the saturation method of determining gene number it will be possible to determine the frequency of globin gene duplication in human populations.

showing that LPS determined the specificity of attachment. The host component of attachment was in the cell wall as purified walls also inhibited tumour formation by competing for bacterial sites. The active fraction was polygalacturonide which was inhibitory at less than 1 ng ml^{-1}. In contrast monocot cell walls gave little or no inhibition of tumour induction, thus the inability of the bacterium to infect this group may result from lack of attachment sites. This is an interesting contrast to results of T. Graham and L. Sequeira (University of Wisconsin) on infection of tobacco by *Pseudomonas solanacearum*, in which avirulent strains attach to mesophyll cell walls and become rapidly enveloped by material, whereas virulent strains remain unattached and multiply freely. Binding may be determined by host

lectins (glycoproteins with diverse properties, for example haemagglutination) which agglutinated avirulent but not virulent cells because of the possession of extracellular polysaccharide by the latter.

Many other aspects of host–parasite interaction were considered, including plant cell wall structure, induction, repression and modification of pathogens' polysaccharidases, lignification, and degradation of fungal cell walls by host enzymes; however, these were discussed in terms of general rather than specific resistance. Some perhaps unexpected results were presented by H. Mussell (Boyce Thompson Institute, New York) implying interactions between pectic enzymes (PG) and host cell walls in specificity for *Verticillium* wilt of cotton; purified fungal PG induced symptoms only in susceptible

cotton cultivars. This may be partly due to the ability of 'resistant' walls to bind rapidly more PG than 'susceptible' walls, and the release of extra proteins, including peroxidase and IAA oxidase (both of which may be involved in symptom expression) from susceptible walls by PG.

Intriguing results were reported on host–symbiont interactions in which recognition and attachment of compatible rhizobia is the first stage before infection and nodulation of root hairs. Most evidence implied that recognition may depend on interactions between root lectins and bacterial surfaces. For example, W. D. Bauer (C. F. Kettering Research Laboratory, Ohio) found that soybean lectin only binds to living cells of symbiotic strains of *R. japonicum* and not to non-symbiotic strains, although there were some exceptions reported by J. Paxton (University of Illinois) and F. B. Dazzo (University of Wisconsin). Albersheim's results implied that the active bacterial surface component is LPS, as lectins from four legume species only interacted with the LPS of their corresponding symbionts. These lectins also had enzymic activity (against LPS) which may be a prerequisite for infection as intact LPS of *E. coli* elicits phytoalexin production; thus lectins may provide not only a physical linkage between surfaces but could trigger other critical events including a localised swelling of bacteria and decrease in respiration rate. Dazzo extended these studies using immunochemical techniques and found a surface antigen unique to infective strains of *R. trifolii* which cross reacted with antigens on roots of its symbiont clover; mutation to loss of infectivity resulted in loss of the antigens. A surface protein from clover roots, trifoliin, is specifically able to bind to the polysaccharide antigen and to agglutinate infective cells, and this probably explains specific adsorption by providing a bridge between the clover and rhizobial antigens.   □

Antarctic ice and desiccation in the Mediterranean

from A. Hallam

ONE of the more spectacular results of the Deep Sea Drilling Project has been the confirmation that the deep Mediterranean basins are underlain by a thick layer of apparently shallow water late Miocene (or 'Messinian') evaporite deposits of the type previously known from neighbouring land areas such as Italy. These evaporites are covered by Pliocene muds containing microfossils indicative of deep water conditions. For several years widely differing views have been put forward to account for such a peculiar deep sea occurrence. Hsu and his associates have argued that the northward convergence of Africa on Europe effectively cut off, about 6.5 million years ago, a series of deep topographic depressions in which, following desiccation, halite and calcium sulphate salts were precipitated in shallow salt pans many hundreds of metres below ocean level. Following the opening of the Straits of Gibraltar in the early Pliocene, Atlantic waters cascaded in to fill the basins and restore more or less normal oceanic conditions. Another school of thought rejects this interpretation, maintaining that the deep sea evaporites were originally deposited close to ocean level and occupy their present position as a consequence of substantial post-Miocene tectonic subsidence.

One means of deciding between these alternative hypotheses is to examine microfossils from deep sea core samples taken from the normal marine deposits directly below the evaporites. If these fossils are closely related to groups known to live at great depths in the present world ocean then it becomes difficult to argue that a shallow Miocene sea dried up and the present Balearic, Tyrrhenian, Ionian and Levantine basins were created by subsequent tectonic subsidence. In the proceedings of a micropalaeontologists' symposium held in Tunis (special issue of *Palaeogeography, Palaeoclimatology, Palaeoecology*, **20**, 1/2; July 1976), Benson reports on ostracods and foraminifera obtained from sub-evaporite core material in the Balearic Basin, which appear to indicate unequivocally water depths in excess of 2,000 m. Similar microfossils have been found in contemporary sediments in the Guadalquivir Basin of southern Spain and suggest a continuous oceanic passage through that region from the Atlantic to the western Mediterranean in pre-Messinian times.

Most of the symposium was devoted to discussing the profound effect that the so-called Messinian 'salinity' or 'desiccation crisis' in the Mediterranean had on marine faunas. The pre-Messinian microfaunas, such as ostracods and planktonic and benthonic foraminifera, were very similar if not identical to Atlantic types. Mass extinction took place during the desiccation catastrophe but repopulation from the Atlantic source commenced in the early Pliocene once normal marine conditions were restored. The effects of the catastrophe on the evolution of individual species could well be intriguing but has still not been fully evaluated.

Most scientists who have considered these extraordinary events in the geologically recent history of the Mediterranean have not sought for a world context, but there appears to be good support for Berggren's suggestion that the Messinian evaporitic phase corresponds with a global fall of sea level. Ecological analysis of foraminifera suggests a 40 m drop, which is in remarkably close agreement with the eustatic fall inferred from oxygen isotope data, due to a phase of growth of the Antarctic ice sheet at this time. It seems as though the structural and topographical situation of the Mediterranean region was such that a comparatively modest drop in sea level was sufficient to isolate it substantially from the world ocean, and well over a million years passed before a further eustatic rise allowed a normal connection to be renewed.

A hundred years ago

THE Association finds a fitting home in Glasgow, which has few rivals either in earlier or later scientific reputation. The force of long-continued scientific traditions, added to the present encouragement given to science, and I must also say, to the nearness of the finest holiday localities, makes this one of the most brilliant of recent meetings. Not only is the total number of members and associates attending very high, over 2,700, but the true chiefs of science are present in great strength. It cannot be said that the Association itself is this year at all below its high aims. The majority of papers are really scientific, and do not emasculate the truth in the effort to popularise it. Discussions have been very interesting, judging from the perseverance with which they have been listened to. The reception given by the people of Glasgow is worthy of the city, although it is possible that in the details and refinements of arrangement, Bristol excelled. This was especially manifested in regard to some of the excursions. But it is evident that the very best efforts of the north have been put forth in every way, and the general result is undeniably successful. The charming situation of the University Buildings, in which all the sections but one hold their meetings, is a very great advantage.

Calculations for cancer radiotherapy with pion beams

J. E. Turner, R. N. Hamm & H. A. Wright*

Clinical trials with negative-pion beams for cancer radiotherapy will begin soon at four special facilities in the USA, Canada, and Switzerland. Negative pions are elementary particles which can be produced in high energy accelerators and which have properties that make them seem promising as a new way of treating tumours. The complex interactions that pions undergo in matter make it difficult to calculate dose patterns produced in a body irradiated by a pion beam and to solve that problem a unique combination of research in high energy physics and medicine is needed. Monte Carlo computer codes developed for radiation shielding and radiation protection studies have been adopted for use in dosimetry and treatment planning with negative pions. In this paper we briefly compare the properties of negative pions with those of other types of radiation and describe some calculations that we have made to help assess the potential of negative pions for cancer radiotherapy.

THE question of negative pions for treating cancer was first raised by Fowler and Perkins in 1961[1]. Although negative pions have been available in some physics laboratories since the late 1940s[2], they have not been produced in sufficient intensity for radiotherapy and the large doses needed for treatment of tumours would have required impractically long irradiation times. Today, however, the first studies of pion radiation therapy are beginning in new facilities at the Los Alamos Scientific Laboratory, at Stanford University, at the Swiss Institute for Nuclear Research, and at the Tri-University Meson Facility in Vancouver[3], as adjuncts to primary research programs in physics. Dose rates at these installations are many times greater than those available before.

Because of the expense and difficulty of producing pions in the laboratory, the number and type of experiments which can be performed to assess their potential for cancer therapy are limited. Furthermore, the complex interactions that pions undergo do not lend themselves to analytical calculations. But the availability of high speed computers with large core memories makes it possible to simulate, on the computer, the traversal of a beam of pions in tissue, and programs have been developed specifically to help in studies with negative pion beams in cancer radiotherapy.

Properties of the negative pion related to therapy

The existence of the pion was predicted on theoretical grounds by Yukawa in 1935 to account for the strong, short range nuclear forces that hold atomic nuclei together[4]. Pions, which have a rest mass 280 times that of the electron, can be charged or neutral and are rapidly destroyed through strong interactions with matter and through radioactive decay. They are produced in collisions of high energy particles. Although there were no machines in the 1930s capable of accelerating

particles to the required energies of several hundred million eV, it was recognised that sufficiently energetic cosmic rays bombard the Earth. The presence of the pion in cosmic radiation was confirmed in 1947 (ref. 5).

There are almost 100 known elementary particles and anti-particles, all of which might, in principle, be used for radiotherapy. Negative pions are now attracting attention because of their special physical properties. Like other charged particles, the depth of penetration of negative pions in a target can be varied by varying their energy, and they deliver a relatively high dose when they stop at the end of their track—in the so-called Bragg-peak region. Unlike most other charged particles, however, a stopped negative pion is attracted by a positive atomic nucleus and interacts strongly with it through the nuclear force. The nucleus absorbs the pion and literally explodes with 140 MeV of energy converted from the rest mass of the pion. Figure 1 shows an early cloud-chamber photograph of charged-particle tracks around a nitrogen nucleus that has captured a stopped negative pion. Nuclear capture at the end of its range is the special property that makes the negative pion of particular interest for therapy.

The fragments produced by the capture give additional dose to the matter surrounding the capture site (Fig. 1). The biological effectiveness of this dose is enhanced by the fact that a substantial fraction of it is deposited at high linear energy transfer, since high LET radiations are generally more effective in producing biological effects. Calculations indicate, for example, that some 15–20 MeV of energy is deposited in tissue within 0.2 cm of the capture site by particles with LET greater than that of a 2-MeV proton (170 MeV cm^{-1})[6].

Furthermore, compared with low-LET, the effectiveness of high-LET radiation in killing cells is not reduced as much by the absence of oxygen. A rapidly growing tumour can presumably outgrow its blood supply and become hypoxic. In these conditions, it is well known that the dose of X rays or other low-LET radiations has to be two or three times higher to achieve the same degree of biological damage as in the aerobic state. Pions, in contrast, seem to offer a much more favourable

Fig. 1 Cloud-chamber photograph of negative pion capture by nitrogen. The pion enters the picture from below and follows a curved path in the magnetic field through which it passes. The star at the end of the track is produced by two alpha particles and two protons. Four neutrons are also produced in the star but leave no visible tracks[7].

"oxygen enhancement ratio". Hypoxic cells can be killed almost as effectively as oxygenated cells with high-LET radiation (for more detailed discussion see ref. 8 and references cited there).

Basis for clinical trials

In using radiation to treat a tumour, the objective is to deliver a large dose over a specified volume in the body and as little as possible elsewhere. In reality, however, the dose patterns obtainable are limited by the physics of the interaction of radiation with matter.

Fig. 2 shows a comparison of dose patterns in water along the axes of beams of ^{60}Co γ rays, 22-MeV X rays, protons and negative pions (based on Raju and Richman[8]). The levels of each kind of radiation are adjusted to give the same average dose over the interval between 7.5 and 12.5 cm. The energy spectra of the proton and pion beams were additionally adjusted to give a constant dose over this interval. The dose from ^{60}Co γ rays builds up in the first few millimetres in the absorber as the number of secondary electrons increases. The dose decreases beyond about 0.5 cm as the radiation is further attenuated and scattered. The curve for the more energetic X rays has a maximum near 3 cm and falls off less sharply with increasing depth. In contrast to the neutral radiations, energies of the charged protons and pions can be controlled so that they stop in the given region, where they deposit the highest dose. Whereas a stopped proton gives no further dose, a stopped negative pion produces additional dose through nuclear capture. The advantage gained by negative pions over protons is illustrated by the fact that the pion dose is considerably smaller between the surface of the target and the region between 7.5 and 12.5 cm.

The factors described so far constitute the theoretical basis for the research and investment in pions in radiotherapy. Medical rationale and plans for clinically treating specific types of neoplasms with negative-pion beams have also been developed[9-11].

Computer codes for use in pion dosimetry

Several computer codes[12-15] are available for making calculations for pion beams incident on a patient or tissue-equivalent phantom. Calculations of pion-dose distributions pose several problems not encountered for other charged particles or conventional X or gamma rays. Because of the violent reactions that pions undergo, dose in the phantom does not readily lend itself to a description by means of simple analytical formula. Knowledge of the dose pattern from one beam-target configuration is of limited usefulness in predicting dose under different conditions. The variety of secondary particles produced— each with its own special properties—also complicates any analytical representation.

We have used a Monte Carlo technique to simulate on a computer the statistical distribution of events which occur to the individual particles in the phantom. By treating several thousand incident particles and the secondary particles they produce, one can thus obtain a detailed physical picture of what occurs in actual experimental conditions. The reliability of this picture depends directly on the reliability of the experimental data used in the calculations.

PION-1 was designed to treat all processes which pions undergo with sufficient accuracy to simulate real pion transport for radiotherapy applications. (It was developed in the Health Physics Division at ORNL and is at present restricted to pions, muons and electrons, with energies up to 125 MeV in materials consisting of H, C, N, and O. Other computer codes, developed in the Neutron Physics Division, are designed to transport pions, muons, protons and neutrons with energies up to hundreds of GeV. These codes use an intra-nucleus cascade model to calculate nuclear reaction products. PION-1, which makes use of some data calculated by the Neutron Physics codes, runs considerably faster than the more general, multipurpose codes.) Experimental values of the cross sections have been used to determine pion–nucleon interactions. These values can be revised or supplemented should data become available. All relevant pion nuclear reactions are programmed into the code: pion absorption, one- and two-nucleon knockout, and charge exchange. When an incident pion enters the phantom, the Monte Carlo technique is used to determine its fate, on the basis of these cross sections. As the pion penetrates the phantom, it undergoes multiple Coulomb scattering and also slows down in accordance with the stopping-power formula for charged particles. Range straggling is also included. When a nuclear reaction occurs, the code selects the type of reaction and the

Fig. 2 Examples of dose patterns in water along the axis of beams of ^{60}Co γ rays (1.33 and 1.17 MeV), 22-MeV X rays, protons (P), and negative pions (π^-).
energies and initial directions of travel of any secondary particles produced. The secondary particles are also followed individually in the calculations. The use of numerical data, rather than nuclear models, allows the program to process particles rapidly.

For analysis, the phantom is divided into a number of sub-volumes. A record is kept in the program of each particle that traverses or stops or starts in every subvolume. The energy deposited, the LET of the radiation, and other physical quantities of interest are tabulated—the Monte Carlo method gives complete physical detail. Parameters for use in cell survival models can also be tabulated. Such data would be prohibitively expensive and difficult to obtain experimentally.

Within the context of negative-pion therapy, PION-1 is versatile. No special assumptions about the beam and phantom geometries are necessary. Pions can have any pattern of incidence on the phantom and any energy distribution up to 125

Fig. 4 Isodose contours for pion beam incident on soft-tissue target.

Fig. 3 Total dose, calculated (smooth curve) and experimental (circles), for CERN negative-pion bema. Radius of the detector was 3 cm. Other curves show various calculated contributions to the total dose. Labels on the curves indicate doses from the following sources: pion ionisation (π^-), heavy particles and protons generated from interactions of pions in flight (h+p), muon contamination (μ_c^-), electron contamination (e^-), heavy particles and protons generated from interactions of stopped pions (stars), and neutrons (n). The beam was assumed to be composed of $63\%\,\pi^-$, $23\%\,e^-$, and $14\%\,\mu^-$ with mean momentum 176 MeV/c(energy 85 MeV) and momentum spread 2.0%.

MeV. (The program can be extended to higher energies, if desired.) Muons and electrons can be present. The phantom can be composed of water, tissue, or other tissue-like material and can have regions of bone, lungs, air cavities, and so on.

The code runs rapidly. In a typical calculation, 10^4 incident pions and all the secondary particles they produce are processed completely. The statistical data are then excellent for plotting depth–dose and isodose contours and for compiling LET distributions and parameters for cell survival. The complete run takes about 10 min on the IBM 360/91. The processing of neutrons requires by far the most time. Without neutrons, the running time for 10^4 pions and the other secondary particles is less than three minutes. In many applications we include neutrons in only a fraction of cases.

Comparison of measurements and calculations with PION-1

Ideally, any calculation technique should be substantiated through detailed experimental checks of its component parts. Because of the complexity of pion interactions, detailed veri-

fications are not feasible. Many of the experiments would be costly and time consuming, while others would be prohibitively difficult.

Some direct comparisons have been made between measured doses and doses calculated with PION-1. Figure 3 shows one such comparison made for an experimental negative-pion beam from the 600-MeV synchrocyclotron at the European Centre for Nuclear Research (CERN) in Geneva, Switzerland. This work was carried out as a collaborative effort between the Health Physics Division at the Oak Ridge National Laboratory and the Health Physics Group at CERN[12]. The top curve, marked 'Calc', represents the dose calculated as a function of depth in a water target used in the experiment. The open circles, designated 'Exp', represent the values of the dose measured experimentally. The computations were performed for a beam mixture of 63% negative pions, 23% electrons, and 14% negative muons. A Gaussian momentum distribution was assumed with a mean value of 176 MeV/c(energy of 85 MeV) and a spread of 2% (that is, half of the particles have momentum within ±2% of the mean). The beam, which was non-uniform, was approximately elliptical in shape with major and minor axes of length 7 and 6 cm. The circular cylindrical detector of radius 3 cm, placed at different depths along the beam axis in the experiment, was simulated in the computations. The calculated individual contributions, which add up to the total dose 'Calc', are also shown in Fig. 3. The curve marked 'π^-' gives the dose that results from the direct ionisation of atoms by the pions in slowing down. The curve 'h+p' shows the dose from heavy recoil particles (atomic mass number >1) and recoil protons produced by pions in flight. (About 15% of the incident pions

Fig. 5 Isodose contours for pion beam incident on soft-tissue target with bone cylinder between 1 cm and 3 cm in the cross-hatched region.
react with nuclei in the target before they reach the end of their range.) The local dose in the stopping region from the charged particles produced by pion capture is shown by the curve labelled 'Stars'. Neutrons, which occur primarily as a result of pion capture, give the dose shown by the curve 'n'. The doses from the muons and electrons in the experimental beam are shown by 'μ_c^-' and 'e$^-$'.

This comparison indicates that the dose from a beam of negative pions can be calculated from the known physics of pion interactions with some degree of confidence. Uncertainty in the calculated dose seems to be comparable to the reproducibility of the experimental measurements. Although direct experimental comparisons with most of the individual contributions shown in Fig. 3 have not been made, the curves are consistent with known physical data. The calculated number and energy spectra[16] of the particles produced by stopped-pion capture by oxygen have been compared with measurements[17] and seem to be in reasonably good agreement.

Dose patterns with negative pion beams

Of more direct interest for therapy are the dose patterns expected in tissue irradiated by different pion beams. Figure 4 shows calculated isodose contours in a tissue target of unit density from a parallel, uniform circular beam (radius 2 cm) of negative pions, having a Gaussian momentum distribution with a 2% spread and a mean energy of 67 MeV. The pions have a mean range of 15.0 cm. The beam is incident from the left, the axis being the line marked 0. The contours have cylindrical symmetry about the beam axis and apply to any plane containing that axis. The levels are shown as fractions, varying from 90% to 1% of the peak dose, 1.79×10^{-8} rad per incident pion, which occurs at a depth of 14.5 cm. The dose is not confined completely to the region directly intercepted by the beam. The beam spreads as it traverses the target because of multiple Coulomb scattering and nuclear reactions, which scatter particles outside the immediate beam area. The neutrons produced can deposit dose many centimetres away from the beam axis. Repeating the calculations but ignoring the neutrons gave virtually the same contours for the levels of 5% of the peak dose and greater. The peak dose itself was reduced, however, to 1.71×10^{-8} rad per pion. The lateral spread of the 1% contour from the beam axis at a depth of 15 cm changed from 4.9 to

4.4 cm when neutrons were neglected.

The presence of air cavities, bone and other regions of different densities in the body can greatly affect dose patterns. Figure 5 shows an example of dose contours when bone (density, 2 g cm^{-3}) is present. The bone is in the form of a right circular cylinder of radius 1 cm, centred on the beam axis between the depths 1 cm and 3 cm, as indicated by the cross hatching in Fig. 5. The same pion beam was used in the calculations of Figs 4 and 5. The peak dose with the bone present is decreased to 1.46×10^{-8} rad per incident pion and occurs at a depth of 12.6 cm as compared with 14.5 cm before. The bone increases the amount of multiple Coulomb scattering and some additional nuclear reactions, causing the dose pattern to be more diffuse in Fig. 5. A systematic study of the effects of tissue inhomogeneities has been completed recently[18,19].

Another complication, which must be assessed in using pions for radiotherapy, results from the neutrons produced from pion capture. The neutrons will travel away from the capture site in a tumour and irradiate healthy tissues elsewhere in the body. The neutron dose delivered to a sensitive organ in the vicinity of a tumour may limit the therapeutic dose that can be given to the tumour. We are now calculating the dose contributions from neutrons for a variety of pionbeam configurations and tumour sizes.

The origin of deuterium

Richard I. Epstein

Center for Astrophysics, Harvard College Observatory and Smithsonian Astrophysical Observatory

James M. Lattimer

Department of Astronomy, University of Texas at Austin and Enrico Fermi Institute, University of Chicago

David N. Schramm

Enrico Fermi Institute, University of Chicago

General nuclear constraints are used to show that deuterium is most likely of pregalactic origin. Big-bang nucleosynthesis is the most plausible source for significant amounts of this isotope, but other, more speculative, sources are not ruled out.

THE amount of deuterium which is formed during the initial phase of a standard hot big-bang universe is a sensitive function of the mean baryon density ($X_D \propto \rho^{-5}$ over the range of interest; X_D is the deuterium mass fraction and ρ is the mean baryon density; (see ref. 1). If big-bang nucleosynthesis were the only significant source of deuterium, the amount of deuterium

produced by this event would have to be at least as great as that which is currently observed, $X_D \sim 2 \times 10^{-5}$ (refs 2 and 3). The mean mass density of the present Universe would then be $< 6 \times 10^{-31}$ g cm^{-3} and hence less than the Einstein–de Sitter critical density $\rho_c = 3H^2/8\pi G = 4.5 \times 10^{-30}(H/50)^2$ g cm^{-3} (H is the Hubble expansion parameter in km s^{-1} Mpc^{-1}). In the framework of Friedmann cosmologies with cosmological constant $\Lambda = 0$ this would mean that the Universe is open and forever expanding[4,5]. Conversely, if the mean density of matter in the Universe is appreciably $> 6 \times 10^{-31}$ g cm^{-3}, the current deuterium abundance could not have been produced by nucleosynthesis during the early phase of a standard universe. These conclusions are insensitive to quite substantial deviations

from the standard cosmological models[6], presuming also that the bulk of the observed [4]He was produced in the big bang.

These statements provide good reason for investigating other possible sources of deuterium. If an exhaustive study yields no physically self-consistent or at least plausible models for deuterium production, then this failure lends support to the notion that deuterium is of cosmological origin. On the other hand, if an eminently plausible source of deuterium production or enhancement could be found, then the current deuterium abundance would not necessarily be related to the physical conditions in the early Universe and hence could not be considered to be an important cosmological discriminator.

We examine here various non-cosmological mechanisms which might be capable of producing significant amounts of deuterium. First, the general nuclear constraints which must be satisfied by all viable models for deuterium production are summarised. Specific models for deuterium sources are then discussed and critically analysed. The net result of this investigation is that very severe restrictions can be placed on mechanisms for producing deuterium. In fact, it seems unlikely that objects or events which are currently known or inferred to have existed in our Galaxy or in well-observed extragalactic objects could be capable of producing the observed deuterium abundance.

Overview

Deuterium formation can occur either through synthesis reactions in which free nucleons fuse together or by means of spallation or photodisintegration reactions in which energetic particles disrupt more massive nuclei, thereby ejecting deuterons. All models of deuterium production invoke one or both of these processes.

Synthesis models run into difficulty because the conditions which are needed for the making of deuterium are normally the same as those for its rapid destruction. Deuterium can be synthesised by [1]H(n,γ)D reactions if free neutrons and protons are able to interact. Free neutrons are produced at high temperatures, when heavier nuclei thermally dissociate, but any deuterium which is so formed is liable to be consumed in thermonuclear reactions. Deuterium could survive a hot explosive event only if the hot matter is dispersed and/or cooled rapidly compared with the time which is required for deuterium destruction. It is shown below that an object of even moderate mass ($\gtrsim 10^{-7} M_\odot$) cannot expand rapidly enough for significant amounts of deuterium to survive. Free nucleons may also be produced by the passage of a strong shock wave[8-10]. In this type of process the gas cools quickly enough for the deuterium to escape destruction, but models which invoke shock waves for deuterium production are faced with a number of other difficulties[11-15] which we also discuss below.

The possibility that a disrupting neutron star could provide a cool flux of particles has been examined (refs 16, 17 and J. M. Latimer and D. N. Schramm, unpublished), but it was found that this type of event cannot simultaneously provide both free neutrons and free protons, and hence cannot produce deuterium. Cameron and Truran (unpublished) have suggested that if hot neutron-rich material could be ejected by MHD processes from a collapsing stellar core[30,31], deuterium production could result. The constraints on this type of model are discussed below.

Spallation

Models which involve the production of deuterium by spallation reactions are faced with the problem that under most conditions the concomitant production of other light nuclei or γ rays is much too rapid. This is an especially strong constraint because deuterium is destroyed by thermonuclear reactions more easily than any other stable nucleus; any subsequent processing of the source material can only decrease the abundance of deuterium relative to other nuclei.

The interaction of energetic particles with normal population-I composition forms deuterium mainly by p + α reactions.

Other light nuclei, such as Li, Be and B, are formed by the interaction of protons or α particles with C, N, or O nuclei and by α + α reactions, and γ rays are formed by high energy p + p reactions producing π° which subsequently decay to two γ rays, each with an energy ~ 70 MeV. By considering the nuclear reactions which can occur in a hydrogen–helium gas mixture only, we can obtain very strong constraints on deuterium source models; these constraints are applicable to deuterium production in the present epoch and in pregalactic but post-helium synthesis epochs. (Deuterium production from spallation is impossible before helium synthesis.)

The rate at which a particle of type i is produced by the interaction of particles j and k is

$$\frac{dY_i}{dt} \propto Y_j Y_k \, \sigma_{i,jk}(E)$$

Here Y represents the number fraction of a particle (Y_i is the number of particles of type i per nucleon; $Y_i = X_i/A_i$ where A_i is the atomic weight), $\sigma_{i,jk}$ is the production cross section and E is the energy per nucleon of the incident particle.

The relative production rate, which is defined by

$$R_i \equiv \frac{1}{Y_{i,\text{present}}} \frac{dY_i}{dt} \qquad (1)$$

gives the rate at which the abundance of a particle approaches the present value. When two nuclei have the same value of R, their abundance ratio at the source is the same as their present cosmic abundance ratio.

The relative production rates for deuterium, [6]Li, [7]Li and γ rays are shown in Fig. 1 as a function of the energy per nucleon of the incident particle. The system is assumed to contain initially only hydrogen and helium with Y_α/Y_P taken to be 0.07 in the energetic particle flux and in the ambient medium. The present densities of the other particles relative to deuterium are $Y_{6\text{Li}}/Y_D \simeq 10^{-5}$, $Y_{7\text{Li}}/Y_D \simeq 10^{-4}$ and $Y_\lambda/Y_D \simeq 10^{-3}\rho_c/\rho$ (refs 18, 19). The last ratio is determined by using the number of photons in the diffuse background with energies > 70 MeV and assuming that the galactic deuterium abundance $Y_D = 10^{-5}$ is universal. It is important to note that in the present epoch there is far more deuterium than there is [6]Li, [7]Li or γ rays. Any class of events which produces even a relatively small amount of these particles cannot be the dominant source of the galactic deuterium.

Fig. 1 The rates at which abundances approach their present values as a function of the energy per nucleon of the incident particle. See equation (1) and text. Data are from refs 19, 28, 29 and C. King, private communication. Dashed lines are extrapolations from known data.
This constraint is clearly shown in Fig. 1. Particle fluxes with energies $\lesssim$ 300 MeV per nucleus generate very large Y_{Li}/Y_D ratios, and particles with energies > 500 MeV per nucleon produce high Y_γ/Y_D ratios. Models for a spallation origin of deuterium must rely on a flux of low energy particles and some mechanism for preferentially destroying the lithium or on a flux of high energy particles and some means of absorbing the γ rays photons. Particles with a narrow spread of energy ~ 400 MeV per nucleon could possibly produce reasonable Y_{Li}/Y_D and Y_γ/Y_D ratios, but models which require nearly monoenergetic particles are rightly considered *ad hoc* and are hard to justify on physical grounds.

It has been pointed out that the γ rays which form from the decay of π^0 can cause the photodisintegration of ^{4}He and thereby produce deuterium[20]. However, the γ rays preferentially produce electron–positron pairs[21,22] so that only a few percent of these photons can ultimately produce deuterium. Since $Y_\gamma/Y_D \sim 10^{-3}$ at present, any model which invokes photo-disintegration to form deuterium must also contain some mechanism for γ-ray destruction. Furthermore, if the π^0 are formed by high energy nuclear collisions, most of the deuterium is actually formed directly by $p+\alpha$ collisions, so that the photodisintegration reaction is of only minor importance.

Finally, it should be re-emphasised that, in the above discussion, the reactions on nuclei heavier than ^{4}He have been omitted. The inclusion of even a small amount of C, N or O nuclei would make it much more difficult to formulate an acceptable model for deuterium formation by spallation. A heavy element mass fraction ~ $Z = 10^{-4}$ leads to over-abundances of Li, Be and B relative to deuterium. This effectively eliminates such events as present-day solar flares[32].

Pregalactic cosmic rays

The high energy particles in the Galaxy could not have produced the galactic abundance of deuterium. The total number of these particles which have existed throughout the age of the Galaxy is far below what is required to produce significant amounts of deuterium, and one is still faced with the difficulty that lithium and other light nuclei would be overproduced. Rather than deal with the restrictive problem of whether deuterium could be formed in any particular type of event, consider the more general question: can one formulate any physically self-consistent model for a cosmic-ray origin of deuterium? The simplest possible model involves 'pregalactic cosmic rays' (only protons and α particles) of arbitrary energy interacting with an ambient medium of hydrogen and helium. A study of this sort has recently been undertaken by Epstein (unpublished) where particle spectra of the form

$$F(E) \propto (E+E_B)^{-2\cdot5} \qquad (2)$$

were used, with E_B an adjustable parameter. This spectral form has the advantage of being a simple one-parameter function which reduces to approximately the galactic cosmic-ray spectrum for suitable values of E_B ($\lesssim 1$ GeV per nucleon). Essentially similar results are obtained by using power law spectra of various indices and with high and/or low energy cutoffs.

When these cosmic rays interact with the ambient medium, deuterons, lithium nuclei, γ rays and other particles are formed. The initial Y_D/Y_{6Li} production ratio is shown in Fig. 2 as a function of E_B (this ratio is used because it provides a stronger constraint than Y_D/Y_{7Li}). Only for $E_B \gtrsim 20$ GeV per nucleon is the initial value of Y_D/Y_{6Li} comparable to the observed ratio. As the system evolves, the proton and α particle spectra are degraded by ionisation losses and nuclear collisions, the deuterons and lithium nuclei which were produced at high energies are slowed down or destroyed, and some of the γ rays are absorbed by the ambient medium. When all relevant production, destruction and energy loss processes are included the Y_D/Y_{6Li} ratio evolves, finally reaching the values indicated
Fig. 2 Ratio of the abundances of deuterium and ^{6}Li which are produced by spallation reactions. The solid line is for spectra defined by equation (2). The dashed line is for spectra which are initially given by equation (2) and subsequently evolve. The observed abundance ratio is indicated.

by the dashed line in Fig. 2. Only for values of $E_B \gtrsim 30$ GeV per nucleon is the final Y_D/Y_{6Li} ratio acceptable. For these very hard cosmic ray spectra γ rays are, however, overproduced by a factor of > 10^4 relative to the diffuse background. Only if the source of γ rays were shielded by ~ 500 g cm^{-2} of matter would the observable flux of γ-ray photons be consistent with existing measurements. The energy which is required to give a deuterium abundance of $X_D = 2 \times 10^{-5}$ is 1.7×10^{18} erg g^{-1}, or 5×10^{62} erg for a $10^{11} M_\odot$ galaxy.

A spallation origin of deuterium cannot be totally dismissed on the basis of the above discussion, but can the necessary conditions for this mode of deuterium formation be realised in any reasonable astronomical event? The intense flux of cosmic rays, the low heavy element abundance and the large column density are certainly inconsistent with what is known about normal galaxies. Quasars, on the other hand, emit roughly the correct amount of energy, much of which is presumably derived from non-thermal particles, and they could provide sufficient shielding (a $10^8 M_\odot$ object with a 6-pc diameter has a column density > 10^3 g cm^{-2}). Observed quasars contain elements heavier than ^{4}He, but an earlier generation of 'extreme population II' quasars could be a possible site for deuterium production. The absorption of γ rays could also be achieved by the general ambient medium of the Universe if deuterium formation occurred at a sufficiently early epoch. This would require that deuterium production occur at redshifts > $z = 300$, shortly after recombination of the ionised matter in the Universe[23]. One can conjecture that an intense flux of high energy particles could be generated by an early generation of collapsing objects[24] or by energetic turbulence which results from the readjustment of the cosmic gas after its decoupling from the radiation field. Without other supportive evidence for such mechanisms, however, their invocation seems, again, quite *ad hoc*.

Shock waves

It has been suggested by Colgate[8,9] and by Hoyle and Fowler[10] that strong shock waves propagating through a low density gas could produce deuterium. The basic idea is that as a shock wave propagates through a low density medium, such as an extensive stellar envelope, it can exhibit a brief non-equilibrium phase in which high energy ion reactions ($\gtrsim 10$ MeV per nucleon) can occur; this 'ion precursor' phase arises partly from the initial collisions between the outwardly streaming ions and the

stationary low density matter, and partly from the relatively long time (compared to a nuclear reaction time) that is required for the shocked gas to relax to thermal equilibrium. As equilibrium is attained through electron heating and photon emission processes, most of the internal energy of the shocked material is transferred to the radiation field and the ions are quickly cooled. During the ion precursor, spallation reactions of protons on helium produce deuterium and free nucleons while spallation reactions on the CNO nuclei and α–α reactions produce Li, Be, and B. In the cool gas behind the precursor the free nucleons recombine to augment the deuterium abundance. Though this mechanism is an ingenious blend of the two basic deuterium production processes it runs into difficulties on several accounts.

First, the very existence of strong ion precursors is in doubt. Weaver[14] has been able to obtain solutions only for the shock wave structures which do not exhibit high temperature precursors. Furthermore, no one has been able to show that shock waves with ion precursors are actually physically self-consistent.

The second problem is that shock-wave nucleosynthesis tends to overproduce some of the light elements relative to deuterium[11,12]. Shock waves of energies up to 50 MeV per nucleon produce deuterium and other nuclei by direct spallation so that ^{7}Li is always overproduced. Stronger shock waves, however, spall nearly all the nuclei to free nucleons, thereby destroying the ^{7}Li overabundance and allowing for the subsequent synthesis of deuterium by ^{1}H(p,n)D. The unresolved question is whether an appreciable amount of matter can be processed by very strong shock waves without an even larger amount of matter being exposed to weaker shock waves which would preferentially produce ^{7}Li. Colgate[25] contends that at low shock velocities the diffusion of radiation damps the development of a precursor (and thus prevents ^{7}Li from forming), and that at high shock velocities the radiation does not keep pace with the shock wave so that the precursor develops and deuterium forms. As mentioned before, the detailed calculations of Weaver do not support this picture.

If the arguments in favour of deuterium production in shock waves were accepted there would still remain the question of what the origin of these shock waves could be. Normal supernovae appear to be highly unlikely sites. Using the most favourable assumptions (low CNO abundances, efficient acceleration of the shock waves) Epstein *et al.*[12] found that energies $> 10^{53}$ erg would have to be released in a typical $5M_\odot$ type II supernova; this is far greater than any observational inferences[15]. Pregalactic supermassive objects could have, perhaps, undergo extremely violent explosions, and few constraints can be put on their energetics. Nevertheless, there is no reason to expect that they could be any better suited for producing deuterium than current supernovae.

Hot explosions

Deuterium can be formed if matter is brought to high temperatures where heavy nuclei decompose to free nucleons ($T > 10^9$–10^{10} K, depending on density) and then rapidly expanded and cooled. The deuterium is formed by ^{1}H(n,γ)D reactions, and it is also destroyed by thermonuclear processes, the most important destruction reactions being (D(d,n)^{3}He and D(d,p)^{3}H as long as $Y_D \gtrsim 10^{-5}$. What fraction of the deuterium which is formed in an explosive event actually escapes destruction? If the densities of neutrons and protons are nearly equal there are two possible sequences by which deuterium can be formed and also survive (the case in which there is a large excess of neutrons is considered later):

(1) The expansion may be rapid enough so that some neutrons and protons do not recombine until the gas cools to the 'freeze-out' temperature ($T \lesssim 3 \times 10^7$ K), when the charged-particle reactions are slower than the expansion. The deuterium which is subsequently formed is ejected without much thermonuclear destruction.

(2) Deuterium forms while the gas is still hot but the expansion

is rapid enough so that deuterium is ejected without being completely destroyed.

Neutrons and protons are consumed at a rate

$$\frac{dY_n}{dt} = \frac{dY_p}{dt} = -4 \times 10^4 \rho \, Y_n Y_p \, \text{s}^{-1} \qquad (3)$$

where ρ is in g cm^{-3}. Define $\rho_0 \tau_{exp} = \int \rho dt$ where the integration is from the time at which the nucleons start being consumed (when $T \gtrsim 3 \times 10^9$ K) until freeze out. The upper limit on the number of free neutron–proton pairs at freeze out and hence on the abundance of deuterium which forms after freeze out is

$$Y_D \lesssim (4 \times 10^4 \rho_0 \tau_{exp})^{-1} \qquad (4)$$

Deuterium which forms at high temperatures is subject to destruction by thermonuclear reactions. The rate at which deuterium is burnt by D + D reactions at $T \sim 10^9$ K is[26]

$$\frac{dY_D}{dt} \simeq -10^7 \rho Y_D^2 \qquad (5)$$

so that the amount of deuterium which forms at high temperatures and survives until freeze out is limited by $Y_D \lesssim (10^7 \rho_0 \tau_{exp})^{-1}$. Since this is far less than the maximum amount of deuterium production after freeze out, equation (4) represents a strong upper limit to the net deuterium production in a hot explosion.

Since only a small fraction of the matter in the Universe could have been raised to high temperatures and then rapidly expanded (except, of course, in the big bang), the deuterium fraction in the ejecta has to be greater than the interstellar value of $\sim 10^{-5}$. Taking the value to be $Y_D > 10^{-3}$ and using equation (4) gives

$$\rho_0 \tau_{exp} < 2 \times 10^{-2} \text{ g s cm}^{-3} \qquad (6)$$

Can such rapid expansion rates be attained in realistic explosive events? To obtain a lower limit to τ_{exp}, consider an homogeneous sphere of mass M and density ρ expanding so that its surface moves with some speed less than the velocity of light. Taking $\tau_{exp} = \rho/(d\rho/dt)$ gives

$$\rho \tau_{exp} \gtrsim 0.9 \, \rho^{2/3} \, (M/M_\odot)^{1/3} \text{ g s cm}^{-3} \qquad (7)$$

The density of matter at 10^9 K has to be $\gtrsim 8$ g cm^{-3} for the energy density of the radiation $> \rho c^2$. (Only in the big bang can this condition be reasonably violated.) Expansion rates which are consistent with equation (6) thus require the mass of the exploding region to be $\lesssim 10^{-7} M_\odot$. Since this is much too small to correspond to any reasonable astronomical event, we conclude that significant amounts of deuterium cannot survive a hot explosion.

Disrupted neutron stars

Can neutron stars provide the free neutrons which are needed for deuterium synthesis? Lattimer and Schramm (ref. 16, and unpublished) investigated a mechanism whereby a neutron star falling towards a black hole (for example, a binary system decaying by gravitational radiation) is tidally disrupted and ejects some neutron-rich matter from the system (the 'tube-of-toothpaste' effect), and others (refs 30, 31 and A. G. W. Cameron and J. Truran, unpublished) have shown how neutron-rich matter can be ejected by MHD instabilities from the collapsing core (a 'hot neutron star') of a highly evolved star. For deuterium to be produced in this type of process the neutron-rich matter has to interact with protons before (1) all the free neutrons are consumed in forming heavy nuclei or (2) before the neutrons decay to protons. Following Lattimer *et al.*[17] it seems that, as the neutron-star matter expands, the few protons which are initially present ($Y_p \simeq 0.03$–0.04) clump

together with the neutrons to form clusters. The excess neutrons 'boil off' until the nuclear clusters reach the neutron drip line. As the density decreases further, β decays begin to occur in the nuclei; the increase in proton number permits the recapture of neutrons. Nuclei up to mass $A \sim 300$ are formed and then fission produces more seed nuclei. Neutrons are consumed as rapidly as permitted by the β decays and fissions of the heavy neutron-rich nuclei. The timescale for this to occur is ~ 0.1 s. (Similar processes occur for the hot neutron star except the initial Y_p are 2 or 3 times larger and the neutron depletion time scales could be considerably longer.) Expansion rates more rapid than this would allow some free neutrons to escape.

Even if some free neutrons do escape, however, they decay in $\sim 10^3$ s and do not produce any deuterium unless they interact with hydrogen-rich matter with a density of at least 10^{-8} g cm^{-3}. Densities of this magnitude are associated with stars or stellar envelopes. Models of deuterium formation which require a large number of neutron stars to interact with black holes and to spew neutron-rich matter into nearby stars are probably beyond the range of reasonable speculation. Hot neutron stars, however, are still surrounded by the pre-supernova stellar envelopes. For the hot neutron-rich material to be able to interact with the overlying hydrogen mantle several conditions must be satisfied: (1) the β-decay rates for very neutron-rich nuclei must be ~ 1 s; (2) the neutrons cannot interact with the heavy elements which surround the core, and (3) the neutron-rich matter has to be ejected rapidly enough so that it can reach the hydrogen mantle (a distance of 10^{10}–10^{12} cm from the core) in $< 10^3$ s. Any or all of these conditions are likely to be violated, but for now this remains a viable model.

Conclusion

Big-bang nucleosynthesis provides an elegant theory for the synthesis of deuterium and helium. It requires only the simplest cosmological assumptions and is consistent with all well established astronomical data. Contrasted to this, post-big-bang deuterium production requires extremely violent and exotic events, the existence of which is certainly doubtful. From the perspective of our current understanding of the chemical evolution of the Universe, big-bang nucleosynthesis is by far the most reasonable site for the origin of deuterium. What are the prospects that this conclusion may be altered or made more firm? Two approaches may be fruitful. First, one can search for direct evidence of post-big-bang deuterium formation such as inhomogeneities in the abundance of deuterium or enhancements in the abundances of lithium, beryllium, boron and γ rays, which may be associated with deuterium production. Variations of this sort either in our Galaxy (ref. 27, and A. A. Penzias, P. G. Wannier, R. W. Wilson and R. A. Linke, unpublished) or in extragalactic objects such as quasars (T. Adams, unpublished) would be of great importance. The results to date

indicate a possible decrease in the deuterium abundance near the galactic centre (A. A. Penzias, P. G. Wannier, R. W. Wilson and R. A. Linke, unpublished); this is consistent with any pregalactic origin of deuterium followed by destruction of deuterium by stellar processing. The second approach, which is being vigorously pursued by a number of researchers (see ref. 5 and references therein), is to determine the local mean mass density of the Universe. Considerations of the dynamics of galaxies and groups of galaxies has led to the tentative result that the mean density is at least 5×10^{-31} g cm^{-3}. If further studies could raise this limit by even a firm factor of two or three (still leaving ρ below the critical density ρ_c), then the standard cosmological picture for the origin of deuterium would have to be seriously questioned and exotic pregalactic or hot neutron star models might have to be invoked.

It may turn out that deuterium was formed during the initial hot phase of the big bang or during subsequent epochs. In either case the abundance of this isotope provides an intriguing clue to evolution of the early Universe.

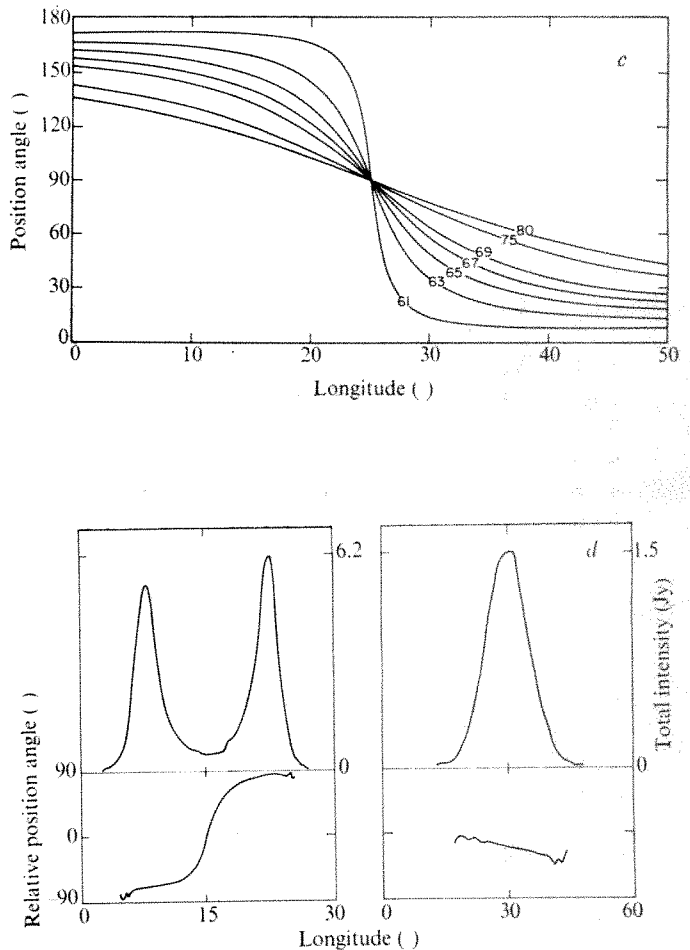
Orthogonal mode emission in geometric models of pulsar polarisation

D. C. Backer
Radio Astronomy Laboratory, University of California, Berkeley, California 94720

John M. Rankin
Astronomy Department, Cornell University, Ithaca, New York 14853

D. B. Campbell
Arecibo Observatory, Arecibo, Puerto Rico 00612

The varying incidence of orthogonal 'states' of linear polarisation across the pulse of PSR 2016 + 28 is discussed in terms of a model with subpulse beams drifting round the pole of a rotating magnetic dipole.

THE position angle associated with the average linearly polarised radiation from many pulsars varies across the pulse in a manner consistent with a simple geometrical model first given by Radhakrishnan and Cooke[1,2]. The model postulates polarised radiofrequency emission having properties character-
Fig. 1 *a*, Schematic representation of the Radhakrishnan and Cooke pulsar model[1]. Emission is associated with the polar regions of an oblique, rotating, magnetic dipole. *b*, Field geometry near the pole of the star projected on to the celestial sphere. The radiofrequency radiation is expected to have polarisation characteristic of curvature radiation from particles accelerated along the field lines[1]. *c*, Model waveforms of linear polarisation angle for a magnetic dipole axis inclined at 60° to the rotation axis; curves for observers at various polar angles are indicated. *d*, 430-MHz Arecibo observations of two pulsars (PSR 0525+21, left; PSR 1915+13, right) with linear polarisation angle morphologies which conform well with the Radhakrishnan–Cooke model angle waveforms in (*c*). The position angles are not absolute.


istic of the radiation from relativistic particles accelerated along diverging field lines near the poles of an oblique, rotating, magnetic dipole. Figure 1*a* shows the general configuration of the two emitting regions and Fig. 1*b* gives a view of the field lines as projected on to the celestial sphere. Position angles associated with the linearly polarised component of the radiation in this model are expected to coincide with the magnetic field projections in Fig. 1*b*. Thus the position angles are expected to progress monotonically through some portion of 180° during the pulse as the rotation of the star carries the polar cone of emission across the line of sight. Figure 1*c* gives model angle waveforms calculated for a dipole inclined at 60° and a range of observer inclinations; Fig. 1*d* presents observations of two objects as examples of the many pulsars which are nominally consistent with the model (see also, for instance, ref. 3).

There is, however, a second class of pulsars which displays more complicated polarisation angle behaviour that cannot be adequately accounted for on the basis of the above geometric model. In particular, there are several objects in the Arecibo pulsar polarisation survey[4] which exhibit a rapid swing in the average polarisation angle by ~ 90° (for example, pulsars 1541+09, 1604−00, 1944+17, 2016+28 and 2020+28, see Fig. 2). Clearly the Radhakrishnan and Cooke model can account for only a single rapid change of ~ 180°. Furthermore,

Fig. 2 430-MHz Arecibo observations of two pulsars which exhibit complex polarisation angle morphology (PSR 1944+17, left; PSR 2016+28, right). Rapid transitions of ~ 90° are evident in both cases. The position angles are not absolute.

Fig. 3 Probability distribution of linear polarisation angle at a sequence of longitudes across the pulse of pulsar 2016+28. Long. is the relative longitude in degrees, $\langle I \rangle$ is the amplitude of the total intensity average waveform in Jy, $A1$ is the vector-average position angle waveform in degrees (also plotted superposed on the distributions for comparison), and $A2$ is the corresponding arithmetic (amplitude independent)-average polarisation angle waveform. The display consists of probability densities of polarisation angle (in units of 10%) (with a decimal point indicating 0.05–5.0%) per resolution cell. The distributions reflect only those data which exceeded an amplitude threshold computed from the off-pulse noise baseline; the final column on the right gives the fraction of data above the noise threshold (in units of 10%).

90° rotation has been found to occur within subpulses of PSR 0809+74 (ref. 5), from subpulse to subpulse in PSR 2303+30 (ref. 4) (two objects dominated by drifting subpulses), and has been noted in several contexts recently[6].

Preferred polarisation angles

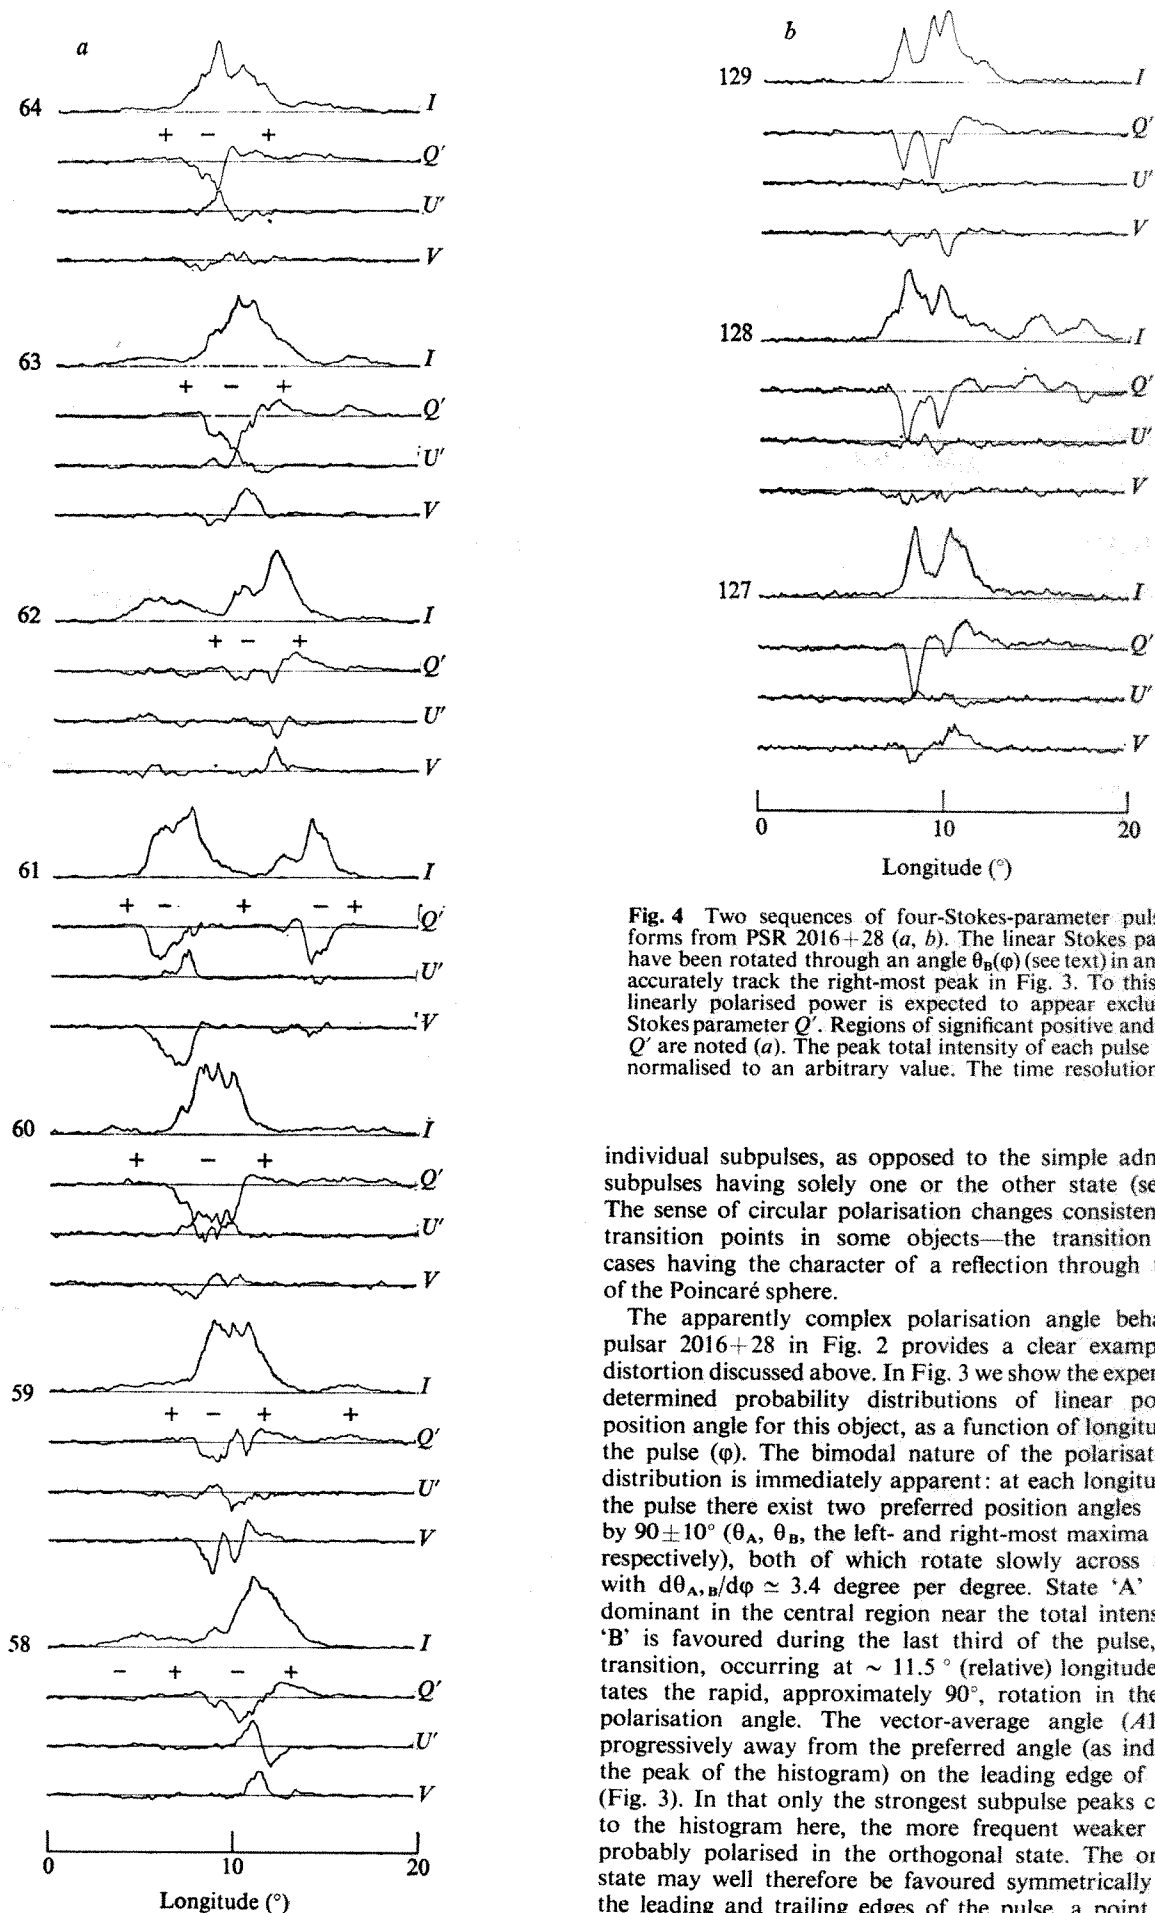
Statistical studies of the Arecibo polarisation survey data[7] indicate that most objects have, at a given longitude (360° longitude = 1 pulse period), two, nearly orthogonal, preferred polarisation angles of emission, and also that the relative proportion of the two '90° states' often changes markedly across the pulse waveform (see also ref. 6). The varying proportion of the orthogonally-polarised constituents serves to distort a 'fundamental' angle waveform which, in most cases, is found to be consistent with the Radhakrishnan and Cooke model. (In other words, angle waveforms computed by averaging the data |90°| (instead of |180°|) would compare well (|90°|) with those in Fig. 1c.) Specifically, the characteristic bimodal nature of the position angle distribution arises, at least in part, from the rapid transition between states within


Fig. 4 Two sequences of four-Stokes-parameter pulse waveforms from PSR 2016+28 (*a*, *b*). The linear Stokes parameters have been rotated through an angle $\theta_B(\varphi)$ (see text) in an effort to accurately track the right-most peak in Fig. 3. To this end the linearly polarised power is expected to appear exclusively in Stokes parameter Q'. Regions of significant positive and negative Q' are noted (*a*). The peak total intensity of each pulse has been normalised to an arbitrary value. The time resolution is 0.5°.

individual subpulses, as opposed to the simple admixture of subpulses having solely one or the other state (see ref. 6). The sense of circular polarisation changes consistently at the transition points in some objects—the transition in these cases having the character of a reflection through the origin of the Poincaré sphere.

The apparently complex polarisation angle behaviour of pulsar 2016+28 in Fig. 2 provides a clear example of the distortion discussed above. In Fig. 3 we show the experimentally determined probability distributions of linear polarisation position angle for this object, as a function of longitude within the pulse (φ). The bimodal nature of the polarisation angle distribution is immediately apparent: at each longitude within the pulse there exist two preferred position angles separated by $90 \pm 10°$ (θ_A, θ_B, the left- and right-most maxima in Fig. 3, respectively), both of which rotate slowly across the pulse with $d\theta_{A,B}/d\varphi \simeq 3.4$ degree per degree. State 'A' is clearly dominant in the central region near the total intensity peak, 'B' is favoured during the last third of the pulse, and the transition, occurring at $\sim 11.5°$ (relative) longitude, precipitates the rapid, approximately 90°, rotation in the average polarisation angle. The vector-average angle ($A1$) moves progressively away from the preferred angle (as indicated by the peak of the histogram) on the leading edge of the pulse (Fig. 3). In that only the strongest subpulse peaks contribute to the histogram here, the more frequent weaker data are probably polarised in the orthogonal state. The orthogonal state may well therefore be favoured symmetrically on both the leading and trailing edges of the pulse, a point which is discussed further below.

Subpulse polarisation

Having investigated the occurrence of the two orthogonally-polarised angle states in the context of the average polarisation angle waveform, it is now clearly of interest to explore the nature of subpulse polarisation in the same light. Since the linear polarisation at any point in the pulse is observed to favour only two orthogonal position angles, the linear Stokes parameters at each point can be defined so that one linear component, say U', is always zero and the other, Q', reverses sign between the two states. This arrangement of the linear Stokes parameters (Q', U') is effected for all longitudes φ by rotating the reference angle from position angle zero to θ_B (φ). Two sequences of pulses from PSR 2016+28, in all four Stokes parameters, I, Q', U' and V, are shown in Fig. 4. From Fig. 4 it can be seen that, although the Stokes parameter U' is imperfectly nulled, the linearly polarised power preponderates in Q' and so our general view seems valid.

Models

We wish to interpret the Q' morphology in terms of the properties of subpulse beams according to the general tenets of the model proposed by Radhakrishnan and Cooke, whose views have been both extended and given a firm theoretical foundation by Sturrock[8] and by Ruderman and Sutherland[9]. In addition, Ruderman[10] explored the possibility that the drifting subpulse phenomenon is produced by narrow subpulse beams circulating round the dipole axis. The dimensions and motions of such subpulse beams seem to be consistent with a hollow-cone average beam—a concept suggested by Komesaroff[2] which now seems to be in agreement with much experimental evidence[11]. Figure 5 summarises the various relevant features of these models in a single drawing where we have yet to speculate on the polarisation structure of the subpulse beams (indicated by $+/-$ signs). Finally, the presence of two unresolved components in the total intensity average waveform of 2016+28 (evident in Fig. 2 as well as in other observations[11]) suggests that our line of sight passes somewhere near the inside edge of the cone as indicated in Fig. 5.

The Q' Stokes parameter

The Q' waveforms in Fig. 4 provide a tracing of the two orthogonal modes of emission (the sense of Q' distinguishing be-tween the two) as the rotation of the star carries the pulsar's polar region across our line of sight. It is evident in Fig. 4a that central subpulses (those near the total intensity peak of the pulse) are most frequently characterised by a large negative excursion of Q', bounded on one or both sides by smaller positive regions. The configuration depicted in Fig. 5 (a, c, e)—that is, a total power beam with a central lobe of one emission state $(Q' < 0)$, bounded symmetrically by two sidelobes of the orthogonal state $(Q' > 0)$—seems to be the simplest time invariant beam largely compatible with the observed subpulse polarisation characteristics. In particular, the subpulse beams in Fig. 5 (h, i) do not reproduce the observations satisfactorily. Depending on the manner in which the line of sight cuts the subpulse beams, $a-e$, there is substantial flexibility in the kinds of subpulses produced: a well centred subpulse beam (Fig. 5c) produces a symmetrical, negative-Q'-dominated subpulse (Fig. 5C), whereas less central beams (Fig. 5a, e) result in increasingly asymmetrical, positive-Q'-dominated subpulses (Fig. 5A, B, D, E). Although it is difficult to identify positive-Q'-dominated subpulses at the extreme leading and trailing edges of the pulse (Fig. 4) because of the low intensity, Fig. 3 provides evidence that the orthogonal $(Q' > 0)$ state was favoured symmetrically at the extremes of the pulse. That the symmetry is not more pronounced seems to indicate that we are able to see subpulse circulation further in the direction of Fig. 5a than in that of 5e. Furthermore, the subpulses of PSR 2016+28 generally seem to consist of one or more micro-pulses[12] which appear to perturb the foregoing picture, often producing a narrower version of the subpulse polarisation beam apparently superimposed on the broader beam. Some examples of subpulses dominated by micropulses can be seen in Fig. 4b. The actual nature of the radiation is doubtlessly much more complicated than we have outlined here and observations with much finer time resolution are required to study polarisation properties at the micropulse level.

Discussion

Although it is not yet clear whether every aspect of the polarisation properties of PSR 2016+28 are typical of pulsars, some generalisations can be made from the observations. Statistical studies similar to Fig. 3 show both that the two orthogonal '90° states' of emission are a characteristic feature of pulsar
Fig. 5 A schematic drawing of the subpulse beam model for PSR 2016+28 under consideration (see text). This is essentially Ruderman's elaboration[10] on the Radhakrishnan and Cooke model[1], wherein subpulse beams are thought to circulate within a hollow-cone average beam, except that we now specifically consider the nature of subpulse polarisation ($+/-$ indicates the two orthogonal lobes of subpulse polarisation). The dashed curve traces the approximate path of the line of sight across the polar emission region. Sketches of subpulse waveforms corresponding to cuts through three of the illustrated subpulse beams (a, c, e) are given on the right (A, C, E), as well as two intermediate cases (B, D). Polarised subpulse lobe structures (h) and (i) do not seem to correspond to the observations.

Longitude

radiation and that a much larger group of pulsars can now be well described by a simple geometric model when the nature of their radiation is appropriately considered. The polarised individual pulse waveforms of PSR 2016+28, as well as other objects with strong drifting subpulse modulation, have a straightforward interpretation wherein subpulse beams with a rigid polarisation pattern are viewed in different orientations as time progresses. Pulsars 1919+21, 1944+17, 2016+28, the second component of 2020+28 and 2303+30 in the Arecibo survey as well as PSRs 0031−07 and 0809+74 in other studies[6] all bear out various features of this view. On the basis of current pulsar models we have suggested one method of producing subpulse beams which change their orientation on the sky as required: narrow subpulse beams with time-invariant polarisation patterns circulate around the dipole axis maintaining a fixed orientation to the plane of the magnetic field. Our speculations regarding the polarised lobe structure of the subpulse beams are less certain but may have some generality. Neverthe-

less, we hope that they will serve to prompt some further theoretical investigations of emission mechanisms and propagation effects[13] in pulsar magnetospheres.

Arecibo Observatory is operated under contract to the NSF by Cornell University.

Structure of locust adipokinetic hormone, a neurohormone that regulates lipid utilisation during flight

Judith V. Stone & William Mordue

Department of Zoology

Karen E. Batley & Howard R. Morris

Department of Biochemistry, Imperial College, London SW7 2AZ, UK

Adipokinetic hormone, isolated from locust corpora cardiaca, has been identified as a blocked peptide: PCA–Leu–Asn–Phe–Thr–Pro–Asn–Trp–Gly–Thr–NH₂. The detailed structure is based on mass spectrometric data, substantiated in part by dansyl-Edman and carboxypeptidase data on thermolytic fragments. This is the first peptide hormone from an insect neuroendocrine organ to be fully characterised.

In insects, it has been shown (for reviews, see refs 1 and 2) that peptide and protein hormones are produced by neurosecretory cells or glandular cells associated with the neuroendocrine system. These neurosecretory cells are in the brain, the corpora cardiaca and the medial nervous system. Much work has been carried out investigating the factors present in the corpora cardiaca, which are neurohaemal organs that both store and release neurosecretory products synthesised in the brain, and contain intrinsic glandular cells producing their own secretions. So far, factors that affect cuticle tanning[3], water balance[4], carbohydrate metabolism[5−7], muscle contraction[8−10] and lipid metabolism[11−13] have all been found in the corpora cardiaca from various insects, and many of these factors have been shown to be of a peptide nature. Until now, however, none of these active substances has been purified and fully characterised. We report here the purification and identification of one of these factors, the adipokinetic hormone from the locust.

The existence of an adipokinetic hormone in locusts, located in the corpora cardiaca and concerned with flight activity, was first suggested by Mayer and Candy[11] and

Beenakkers[12]. During the initial stages of flight, before release of the hormone, energy is derived from trehalose in the haemolymph[14]. A few minutes after the commencement of flight, however, the hormone is released from the intrinsic secretory cells located in the glandular lobes of the corpora cardiaca[13] into the haemolymph; this hormone has two separate sites of action. It causes the release of specific diglycerides from the fat body[15,16] into the haemolymph. These diglycerides, which are transported as lipoproteins in the haemolymph[17], are used by the flight muscle as a source of energy. The adipokinetic hormone also stimulates the utilisation of these lipids by the flight muscle[18]. Consequently, the hormone is important in the maintenance of prolonged flight activity, by enabling the locust to utilise its lipid stores for energy. Mayer and Candy[11] first indicated that adipokinetic hormone was a peptide as its biological activity was destroyed by proteolytic enzymes.

Isolation

Throughout the purification procedure the hormone was located by measuring its lipid-mobilising activity when injected into adult male *Locusta*. Samples to be injected were dissolved in 20 μl simple insect saline (7.5 g NaCl + 0.375 g KCl l^{-1}). Aliquots (5 μl) of haemolymph were withdrawn immediately before and 1 h after injection of the samples and the changes in haemolymph lipid content measured as described previously[13]. A unit of adipokinetic activity was arbitrarily defined as the quantity of hormone that causes the release of 1 μg lipid per μl haemolymph in 1 h.

The hormone was isolated from the glandular lobes of the corpora cardiaca from both the migratory locust, *Locusta migratoria*, and the desert locust, *Schistocerca gregaria*. The material extracted from 3,000 corpora cardiaca (750 μg)
Fig. 1 Separation of an extract of locust corpora cardiaca on G-75-50 glass beads. The residue from a methanol extract of the glandular lobes from 500 locusts was dissolved in 1 ml distilled water and applied to a column (2×25 cm), equilibrated and eluted with water. Flow rate 30 ml h^{-1}. The effluent was collected in 2-ml fractions. The adipokinetic activity of every third fraction, diluted 1:49 with simple saline was measured, taking the mean response from 4 test insects. —, A_{206}; ●, adipokinetic activity; ⊢——⊣, pooled fractions.

has been used to characterise the hormone fully. The glandular lobes were dissected out under simple saline and placed in methanol. The tissue was disrupted using an MSE 100W ultrasonic disintegrator, and the insoluble debris removed by centrifugation. Methanol was evaporated from the supernatant and the residue redissolved in distilled water. This aqueous extract was applied to a controlled-pore glass bead column (G-75-50 beads, Sigma) and the column eluted with distilled water. A profile as shown in Fig. 1 was obtained. The hormone was eluted as a single peak at an elution volume slightly less than the total column volume. The active fractions were pooled and water was removed under reduced pressure at 50 °C. The residue was dissolved in methanol and applied to a silica gel thin-layer plate prewashed with methanol. The chromatogram was developed in isopropanol–water–acetic acid (25:10:1 v/v) which separated out an ultraviolet-absorbing area of R_f 0.67 that contained the adipokinetic activity. The active material was eluted into methanol and subsequently shown to be the pure hormone. The purification procedure, showing the recoveries of active material at each stage, is summarised in Table 1. Overall, approximately half of the original adipokinetic activity in the glandular lobes was recovered by this method.

Between 100 and 250 pmol (calculated from the amino acid content) of the pure hormone were obtained from one *Locusta* compared with 200–250 pmol from one *Schistocerca*. Taking into account the losses during purification it is estimated that the glandular lobes from the corpora cardiaca of one adult *Locusta* contain 0.25–0.55 μg stored hormone, whereas each adult *Schistocerca* contains 0.50–0.80 μg.

Structure elucidation

Analysis of the hormone after acid hydrolysis gave the amino acid composition shown in Table 2a and suggested it was a nonapeptide. The amino acid compositions of the peptides isolated from both *Locusta migratoria* and *Schistocerca gregaria* were found to be almost identical. The hormone did not react with dansyl-chloride[19] and in electro-

phoresis at 50 V cm^{-1} in formate buffer (pH 2.1) on Whatman number 1 paper, it moved with the neutral marker, 1-diaminonaphthalene-sulphonic acid (DNS-OH). It also coelectrophoresed with the neutral marker alanine at pH 6.5 (pyridine–acetate buffer), the peptide being located in each instance by staining with starch–iodide after chlorination[20]. These results suggest that the peptide does not possess any free amino or carboxyl groups.

The blocked N-terminal amino group of the hormone prevented direct determination of the sequence using the dansyl-Edman procedure[19]. Enzymatic digestion of the peptide with thermolysin for 4 h at 37 °C (120 nmol hormone, 1.2 nmol thermolysin in 500 μl 0.067 M NH₄HCO₃ containing 2.5 μmol CaCl₂), caused the appearance of a residue with a free amino group, identified as phenylalanine using the dansyl-chloride procedure. Electrophoresis of the digest at 50 V cm^{-1} on Whatman 3MM paper at pH 6.5 followed by staining, showed two fragments—one acidic with a mobility of +0.55, and one basic with a mobility of −0.29, relative to aspartic acid. Electrophoresis at 50 V cm^{-1} on Whatman number 1 paper at pH 2.1, also indicated the presence of two fragments, one which moved with the neutral marker, DNS-OH, and the other with a mobility of +0.37 relative to dansyl-arginine. Crude molecular weight determinations from these electrophoretic mobilities[21,22] indicated a value of approximately 350 for the acidic (N-terminal) fragment and 700–800 for the basic (C-terminal) fragment. Elution of these peptides from the electrophoretogram gave an 80% yield of the N-terminal fragment and 20% of the C-terminal fragment. The amino acid compositions of the fragments after acid hydrolysis are shown in Table 2b and c.

The N-terminal fragment was degraded sequentially from its C-terminal end by enzymatic digestion, and the digests analysed on the amino acid analyser without previous hydrolysis. Incubation of 9 nmol of this fragment with penicillocarboxypeptidase-SI (ref. 23) for 3.5 h at 37 °C (in 100 μl 0.2 M pyridine-acetate, pH 4.2, containing 0.15 nmol penicillocarboxypeptide-SI) released 8.7 nmol of a ninhydrin-positive substance, identified as asparagine using the dansyl-chloride procedure. Incubation of 8 nmol of the fragment

Table 1 Purification of adipokinetic hormone from glandular lobes of locust corpora cardiaca

Fraction	Total adipokinetic activity (units)	s.e. of estimate (%)	Recovery (%)
Methanol extract	1,158,300	14	100
Pooled column fractions	982,800	5	85
Thin-layer chromatography fraction, R_f 0.67	649,300	12	56

Values are for a preparation from the glandular lobes of 500 locusts.

Table 2 Amino acid composition after acid hydrolysis of adipokinetic hormone and fragments obtained by thermolysin digestion

	a	b	c
		Relative molar quantity in:	
Amino acid	Hormone	N-terminal fragment	C-terminal fragment
Asp	1.82	1.07	1.15
Thr	1.82		1.71
Glu	1.11	1.49	
Pro	0.96		1.00
Gly	1.05		1.71
Leu	1.00	1.00	
Phe	0.97		0.77

Hydrolyses were carried out in 6 M HCl containing 0.1% phenol. Results are expressed relative to Leu = 1.00 for the hormone and N-terminal fragment, and relative to Pro = 1.00 for the C-terminal fragment.
Fig. 2 Mass spectrum at a source temperature of 250 °C of a permethyl derivative of adipokinetic hormone. · · · Asn, · · · Phe and · · · Trp refer to an N–C cleavage fragmentation pathway[25,29].

with (DFP)-treated carboxypeptidase A (prepared by the second procedure of Ambler[24]) for 24 h at 37 °C (in 25 μl 0.2 M NH$_4$HCO$_3$ containing 80 pmol carboxypeptidase A) released 3.8 nmol asparagine and 0.8 nmol leucine. This shows that the fragment has the sequence –Leu–Asn at its C-terminal end, leaving glutamic acid as the N-terminal residue. The N-terminal amino group of this residue is blocked in some way, as it does not react with dansyl-chloride.

The amino acid sequence of the C-terminal fragment was first investigated using the dansyl-Edman degradation procedure. This indicated the sequence Phe–Thr–Pro–Asn– for the first four residues.

So far a partial structure for adipokinetic hormone could be written as: X–Glx–Leu–Asn – – – – Phe–Thr–Pro–Asn–, where X represents some blocking group and the dashed line a probable linkage between fragments. An additional threonine and a glycine residue present in the amino acid analyses of both the intact hormone and the C-terminal thermolytic fragment remained unaccounted for.

Mass spectrometric methods[25] were applied both to the thermolytic fragments and to the intact hormone to determine its overall structure.

Blocked N terminus

Examination of the acetyl-permethyl derivative[26] of a thermolytic digest of adipokinetic hormone was made using the mixture analysis fractional distillation technique[27,28]. Low temperature scans showed an N-terminal sequence fragment at m/e 98 which together with a weak signal at m/e 126 is characteristic of an N-terminal pyroglutamic acid residue.
When the associated signal m/e 126 is weak as here, this shows conclusively[25] that the N-terminal residue is a pyrrolidone carboxylic acid (PCA) residue before derivative formation. After these signals, a sequence PCA–Leu was established using a signal at m/e 253.

At higher source temperatures a second component volatilised giving a mass spectrum with signals at m/e 204, N-terminal Phe; at 333, Phe–Thr; at 430, Phe–Thr–Pro; and at 586, Phe–Thr–Pro–Asn.

Other signals in the spectrum provided firm evidence of the presence of an additional amino acid residue, other than those in the amino acid analysis of the acid hydrolysate of adipokinetic hormone (Table 2).

Complete structure and the presence of tryptophan

The mass spectrum described above and all spectra of the intact hormone derivatives (see below) contain strong signals at m/e 144, 184, 214 or 215 (refs 25 and 29), (or the signals of their deuterated equivalents), together with sequence ions, which imply the presence of tryptophan in adipokinetic hormone. Although unexpected, it could readily be placed in the sequence by analysis of the 'thermolytic' and 'intact hormone' spectra. For example, the spectrum described above, interpreted as Phe–Thr–Pro–Asn, contained further signals showing that the asparagine is followed in sequence by tryptophan. In one of the thermolysin digests examined, this tryptophan was C-terminal (m/e 215), although it was not in the studies of the undigested hormone as shown below. The presence of this tryptophan was confirmed and the sequence was extended to the true C terminus by analysis of the spectra of the intact hormone derivatives.

Figure 2 shows the mass spectrum of the acetyl-permethyl derivative[26] of intact adipokinetic hormone, and was interpreted as follows: Abundant sequence ions at m/e 98, 253, 409, 570 and 699 are readily assigned to PCA–Leu–Asn–Phe–Thr as the N-terminal sequence, confirming the blocked N terminus and the presumptive Asn–Phe bond assumed from the thermolysin data. Other major
Fig. 3 Mass spectrum at a source temperature of 270 °C of a perdeuteromethyl derivative of adipokinetic hormone. Mass shifts are correlated with signals in Fig. 2 to support the assignments made. For details see text.

signals in the spectrum derive from N–C cleavage pathways[25,27] which originate from signals at m/e 126 (asparagine), 131 (phenylalanine) and 184 (tryptophan).

The most important of these N–C cleavage pathways, as regards interpretation of structure, is that emanating from tryptophan at m/e 184. Testing for amino acid mass differences from m/e 184 the first major unassigned signal is at m/e 255, a glycine mass difference away. That this signal could be due to a threonine residue eliminating its side chain with rearrangement, is unlikely, as neither a threonine sequence ion (m/e 313) nor an associated loss of methanol (m/e 281) are present in the spectrum. Moving from m/e 255 to higher mass, m/e 384 can be assigned to a threonine mass difference, losing the expected 32 mass units (CH₃OH) to give the smaller signal at m/e 352. The reason for m/e 370 not being assigned to a serine residue is that no expected loss of 32 from this signal is observed. After m/e 384 a 44 mass unit difference to m/e 428 is assigned as a C-terminal amide in adipokinetic hormone (an ester would have given a signal at m/e 415). The assignment of m/e 428 to the structure shown below is fully substantiated by the expected losses of methanol (m/e 396) and the threonine side chain (m/e 370).
Probably the most powerful confirmation of low resolution structure assignments in mass spectrometry is made by observing the shift in signals associated with the synthesis of deuterated derivatives[30]. The mass spectrum of perdeuteromethyl adipokinetic hormone is shown in Fig. 3. Although the overall appearance of the spectrum is slightly changed by temperature and derivative procedure effects, all the major assignments made in Fig. 2 are vindicated by

the correct mass shift of the corresponding signals. In particular, m/e 187, 261 and 446 in Fig. 3 have moved by 3, 6 and 18 mass units, as would be expected from the structure shown above, and justify the assignment of C-terminal Trp–Gly–Thr–amide. The presence of tryptophan in adipokinetic hormone has since been confirmed both after acid hydrolysis in the presence of 2% thioglycolic acid[31] (30% tryptophan recovery), and after hydrolysis in p-toluene sulphonic acid[32] (50% recovery). Summarising the fragmentation data of Figs 2 and 3 the overall structure of adipokinetic hormone is shown to be: PCA–Leu–Asn–Phe–Thr–Pro–Asn–Trp–Gly–Thr–NH₂. The hormone is therefore a blocked decapeptide and its molecular weight is 1,158.

Biological activity

The biological activity of the fragments produced by thermolysin digestion of the hormone was investigated and compared with the activity of the natural hormone. Figure 4 shows a dose–response curve for pure adipokinetic hormone injected into adult male *Locusta*. At doses above about 5 pmol of hormone the response is near maximal. Doses of the thermolytic digest containing up to 30 pmol of each fragment, however, did not elicit any lipid-mobilising response when injected into locusts. (Thermolysin was inactivated by boiling before injection of the sample.) Consequently, it seems that cleavage of the hormone between its third and fourth residues completely destroys its biological potency, as neither of the resulting fragments possesses any adipokinetic activity.

It is clear that biologically active peptides are components of various control in insects. It was not until relatively recently, however, that any such peptide had been isolated in sufficient quantity for its molecular structure to be determined. The amino acid sequences of a 27-residue peptide from the male fruit fly's accessory gland that influences female mating behaviour[33], and of a pentapeptide that is a proposed neurotransmitter in the cockroach[34], have both been elucidated. To our knowledge the data presented here form the first instance of the complete characterisation of an insect neurohormone. This elucidation of the detailed structure of an insect peptide hormone may be the first step in development of new ways to control
Fig. 4 Dose–response curve for locust adipokinetic hormone. Samples of the pure hormone, dissolved in 20 µl simple saline, were injected into 16-d-old adult male *Locusta*. Each point represents the mean activity ±s.e. from 6 animals.

insect pests. Once the structure–activity relationships are resolved, it may be possible to design compounds which interfere specifically with the normal functioning of the insect neurosecretory system; such interference will d'srupt many morphological, metabolic and physiological events. Indeed it has been shown that treatment with conventional insecticides provokes the release of large quantities of neurohormones, and it is suggested that such release may be the, or a contributory, cause of death[35,36].

The cerebral neurosecretory cell–corpus cardiacum complex in insects is analogous with the hypothalamic–neurohypophysial system in vertebrates[37]. Therefore it is of particular interest that the insect hormone identified here possesses features in common with certain hormones secreted by the hypothalamus. Thus both the N-terminal pyroglutamic acid residue and the C-terminal amide shown for adipokinetic hormone in the present paper, are also seen in thyrotropin-releasing hormone[38,39] and luteinising hormone-releasing hormone[40,41]. A recently characterised crustacean neurohormone, the red-pigment-concentrating hormone from shrimps[42], also possesses these features. Moreover, in spite of its different biological function this shrimp hormone has a similar amino acid sequence to adipokinetic hormone (adipokinetic hormone: PCA–Leu–Asn–Phe–Thr–Pro–Asn–Trp–Gly–Thr–NH_2; shrimp hormone: PCA–Leu–Asn–Phe–Ser–Pro–Gly–Trp–NH_2). Some

early experiments[43,44] in which extracts of insect corpora cordiaca caused a bleaching effect when injected into shrimps emphasises the similarity in structure of these two hormones. Further characterisation of hormones is clearly necessary before it can be ascertained whether close structural relationships exist among all arthropod neurohormones.

The synthesis of adipokinetic hormone is in progress. It is expected that the synthetic peptide will confirm the structure of the hormone postulated here.

3' Non-coding region sequences in eukaryotic messenger RNA

N. J. Proudfoot & G. G. Brownlee

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

The sequence A–A–U–A–A–A is present in six different purified messenger RNA molecules (specifically the α- and β-globulin mRNAs of rabbit and human, the immunoglobulin light chain mRNA of mouse (MOPC 21) and the ovalbumin mRNA of chicken) about 20 residues away from the 3'-terminal poly(A) sequence. In addition, a large selection of the 3' non-coding regions of rabbit and human globin mRNAs (both the α- and β- globin mRNAs) are 85% homologous, demonstrating that this region is significantly conserved in evolution.

EUKARYOTIC mRNAs have been shown to contain several surprising structural features. For instance, they contain modified terminal sequences, specifically the 3' terminal poly(A)[1] and the 5' terminal m⁷Gppp or cap structure[2,3], both of which are added to mRNA post-transcriptionally. In addition, mRNA from higher organisms has been shown to contain substantially more sequence than is required to code for protein. A generalised diagram of the organisation of the various regions in mRNA is shown in Fig. 1.

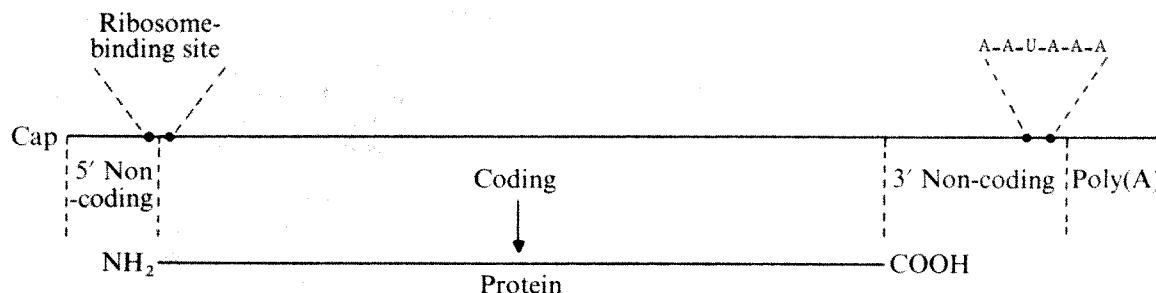
The cap structure and at least a part of the 5' non-coding sequence are thought to be involved in the binding of the mRNA to the ribosome in the correct initiation of protein


Fig. 1 Generalised diagram of a mRNA molecule. There are, however, exceptions to this general arrangement. For example, histone mRNAs lack poly(A) and polio mRNA lacks Cap[4]. See text for explanation of ribosome binding site and A-A-U-A-A-A.

synthesis[4]. The details of these processes are, however, still unknown. Thus a region of about ten nucleotides, referred to as the 'ribosome-binding site' (Fig. 1) seems to base-pair with a sequence at the 3' end of the 16S ribosomal RNA in *Escherichia coli*[5,6]. Although such a process has yet to be demonstrated in higher organisms, it would seem likely that such an important mechanism would be conserved in evolution.

In contrast to the 5' non-coding region, the function of at least a part of which the sequence is known, there is no direct information on the function of the 3' non-coding region. This is surprising as the 3' non-coding region is longer than the 5' non-coding region—at least with the globin mRNAs, for which reasonably accurate estimates have been made[7]. To find out more about this part of the structure of mRNA we have developed a method that has enabled us to determine the sequence of that part of the 3' non-coding sequence which lies immediately adjacent to the poly(A)[8,9]. By comparing this sequence from a number of different mRNAs we have attempted to locate common features which might indicate regions with particularly important functions. We therefore present here sequences of varying lengths adjacent to the poly(A) of rabbit α and β globins[7,9], human α and β globins (N.J.P. and J. I. Langley, unpublished), mouse immunoglobulin light chain[10] and chicken ovalbumin[11] mRNAs. A comparison of particular interest was that of the sequences of the globin mRNAs in rabbit and man. If these 3' non-coding sequences showed reason-

able evolutionary stability this would argue for their importance functionally.

Sequence homologies

Figure 2 shows the sequences adjacent to poly(A) for the six mRNAs, specifically rabbit α and β globins, human α and β globins, mouse immunoglobulin light chain (MOPC 21) and chicken ovalbumin mRNA. All six mRNAs possess the homologous sequences A-A-U-A-A-A (enclosed in boxes) between 14 and 20 nucleotides from the poly(A) sequence. In addition, human β-globin mRNA and chicken ovalbumin mRNA have a more extensive region of sequence (Fig. 3). In detail a region of 13 nucleotides is completely homologous, save one nucleotide, for the two mRNAs. It is also interesting, although possibly less significant, that the other four mRNA sequences have an additional G residue conserved on the 3' side of the homologous sequence: A-A-U-A-A-A-G (Fig. 2).

Another region of partial sequence homology between the six mRNAs is the sequence directly adjacent to the poly(A). Thus five of the six mRNAs possess the sequence G-C-poly(A). The immunoglobulin light chain mRNA, however, does not possess this sequence. This result is a correction to a previous publication[10] in which a single G residue was incorrectly inserted. Thus mRNA can have different sequences adjacent to poly(A), a result in agreement with other studies[16,17].

Fig. 2 Comparison of sequences adjacent to poly(A) in six eukaryotic mRNAs: *a*, rabbit α-globin; *b*, rabbit β-globin; *c*, human α-globin; *d*, human β-globin; *e*, mouse immunoglobulin light chain; *f*, chicken ovalbumin mRNAs. The full sequences of the globin mRNAs are shown in Fig. 4, whereas those of the immunoglobulin light chain and chicken ovalbumin mRNAs are presented elsewhere[10,11]. Boxed sequences denote homology, whereas underlined sequences denote partial homology. Numbers indicate distance from poly(A). The sequence analysis of the six mRNAs is described in detail elsewhere (refs 7, 10 and 11, and N.J.P. and J. I. Langley, unpublished). Each mRNA was copied into ^{32}P-labelled cDNA using DNA polymerase I (*E. coli*) in the presence of Mn[2+] and α-^{32}P-labelled deoxyribonucleoside triphosphates with oligo(dT)[10] as primer[8]. In such conditions, short transcripts of the mRNAs were obtained (50–100 nucleotides long) complementary to the 3'-terminal regions of the mRNAs[7]. These cDNA molecules were then digested with endonuclease IV (refs 12 and 13) and the products obtained were sequenced using standard DNA sequencing procedures[13-15]. Note that the mouse immunoglobulin light chain and the rabbit α- and β-globin sequences contain corrections to previously reported sequences[9,10]. These mistakes were detected by improvements in the sequencing methodology[7,11].

Fig. 3 Comparison of a small section of human β globin (*a*) and chicken ovalbumin mRNAs (*b*). Outside box encloses homologous sequence, inside box encloses sequence common to all six mRNAs. Numbers denote distance of that nucleotide from poly(A) sequence.

Comparison of human and rabbit sequences

One direct test as to the functional importance of a particular nucleotide sequence is to establish how conserved or otherwise that sequence is among different species. If the sequence has completely diverged as in the case of satellite DNA[18] its function may be regarded as not sequence specific. Alternatively if the sequence has been very highly conserved, its function can be considered to be highly specific, and central to the overall biological role of the molecule. Such may be the case with the 3′ non-coding regions of globin mRNA. Figure 3 compares the nucleotide sequences determined for our own and other studies for rabbit α- and β-globin and human α- and β-globin mRNAs. As indicated, the sequences of these 3′ non-coding regions are not yet completely known as there is a gap of about 50 nucleotides in both α-globin mRNA sequences and another of 50 or more nucleotides in the β-globin mRNA sequence[7]. Nevertheless, sufficient of the sequence is known to make a preliminary comparison of the data informative.

Both the α- and β-globin mRNA sequences are extensively conserved between human and rabbit. Indeed, of

129 nucleotides from the 3′ non-coding sequences, only 11 substitutions occur. In addition, there are four examples of deletions and insertions of between one and three nucleotides. This may be regarded as 15.5% nucleotide sequence variation between the two species.

One way of assessing the significance of this figure of about 15% is to compare it with the extent of divergence of the respective coding regions. There is, however, insufficient sequence data available at this time to make such a direct comparison possible. Alternatively the coding regions of these mRNAs may be considered in two parts: those nucleotides that on mutation would cause an amino acid replacement, and those that would not (neutral mutations). From amino acid sequence data on rabbit and human globins[21] the number of mutations causing amino acid substitutions between the two species may be calculated as 5.9%. Furthermore, Paddock *et al.*[22] have compared their limited sequence data on rabbit globin mRNA with the sequences determined for human globin mRNA by Marotta *et al.*[23]; and have suggested that the degree of neutral mutation is much larger, as much as 55%. Further sequence data are required to check this figure. From this preliminary conclusion it follows that the 15% divergence shown here in the 3′ non-coding regions is a larger divergence than is allowed in those nucleotides which would change the amino acid sequence, but a smaller divergence than occurs in the degenerate (neutral) nucleotides. The significance of this in terms of function is probably that the 3′ non-coding region is under less selective pressure than the nucleotides specifying amino acid sequence. This is perhaps not surprising. But equally the 3′ non-coding region is much more conserved than are the nucleotides which are degenerate in the triplet code.

The above conclusions are preliminary because the complete 3′ non-coding sequence is unknown. Indeed it is quite

Fig. 4 Comparison of human and rabbit globin mRNA sequences: *a*, α mRNA; *b*, β mRNA. H, Human; R, rabbit; X, base change between human and rabbit; +, addition of sequence; −, deletion of sequence. With α-globin mRNA sequences, termination regions for the two species are also compared and the position of the carboxy-terminal amino acid sequence of α globin (the same for both species, see ref. 23) is positioned. The mRNA sequence connecting the termination regions with the 3′-terminal regions is indicated by a line. The nucleotide sequence determination of the rabbit and human globin mRNA 3′-terminal regions is described in detail elsewhere (ref. 7 and N.J.P. and J. I. Langley, unpublished). The termination sequence for the rabbit α-globin mRNA has been determined by N.J.P. (unpublished), whereas the human α-globin termination sequence has been established by others[19,21].

possible that only the termination region and the sequence adjacent to poly(A) is conserved at the 15% level, whereas there is a greater sequence variation in the rest of the 3' non-coding region.

Discussion and conclusions

The A–A–U–A–A–A sequence present in all six mRNA 3' terminal sequences seems to display the most significant sequence homology between mRNAs. As this sequence has been demonstrated in four different species—human, mouse, rabbit and chicken—it seems likely that it is present in all eukaryotic mRNA, although further work will be necessary to be completely certain. The biological functions of this sequence remain unknown, although one may speculate from its proximity to the 3' end of the mRNA that it is a signal for an enzyme involved either in the synthesis or processing of mRNA from its presumed precursor[4]. The conservation of sequence between the 3' non-coding sequences of human and rabbit globin mRNA further suggests that much of this non-coding sequnce, in addition to the A–A–U–A–A–A sequence, might possess defined sequence-specific functions. As much of the non-coding sequences described above are not homologous for different mRNAs, however, these functions may be specific to individual mRNAs rather than common to all.

The direct sequence analysis of complementary DNA (cDNA) has provided, and no doubt will continue to provide, a powerful method for the sequence determination of eukaryotic mRNA. This method, as with others[23,24], has, however, certain limitations. In particular the 5'-terminal regions of mRNA are particularly inaccessible when priming the synthesis of cDNA with oligo(dT) hybridised to the 3' terminal poly(A). It may be feasible, however, to over-

come this problem by using primers complementary to other regions of mRNA. Also, it is now possible to sequence cDNA that has been inserted into a bacterial plasmid[25–28]. Such DNA sequences are in a double-stranded state and are therefore susceptible to restriction enzyme digestion and the new rapid DNA-sequencing procedure described by Sanger and Coulson[29].

We thank E. M. Cartwright for assistance. N.J.P. is a junior Beit Memorial Fellow.

Effects of physical adsorption on porous interstellar grains

SOLID grains in space are likely to be highly porous in character. Data from meteorites[1], micro-meteoritic trajectories[2], as well as from comets[3] provide indirect evidence that Solar-System grains are porous and a similar porosity is to be expected for interstellar grains. This would have important consequences for interstellar molecular hydrogen formation, and for the expected densities of noble gases in meteorites:

The effects of porosity in laboratory materials such as zeolites, silica gels and active carbons have been studied for many years[4], mainly with a view to exploiting their properties as adsorbents and molecular sieves. Adsorbant pores are voids in solids which usually communicate with each other. Pore sizes range from 1,000 Å (macropores) to a few Å (micropores). The distribution of pore sizes to be expected in astrophysical solids depends on the mechanism by which they form. The sticking together of separate refractory grains embedded in a matrix of volatile ices or polymers which subsequently partially evaporate because of heating, could result in macroporous structures, as shown in micro meteorites (mass densities ~0.3 g cm^{-3}). Microporosity with pore dimensions < 10 Å may result from the thermal dehydration of originally hydrated mineral crystals (for example zeolites or silica gels).

For macroporous grains the total effective adsorption area could be increased by an order of magnitude, but the physisorp-

tion energy remains unaltered. Microporosity, on the other hand, leads to enhancement of effective physisorption energy by a factor of ~5 in a typical case (Fig. 1, ref. 4), together with an increase of the adsorption area of a grain by a few orders of magnitude. The surface area per unit mass for non-porous spherical grains of radius a, density s is $3/as$. For typical values $a = 1.5 \times 10^{-5}$ cm, $s = 2$ g cm^{-3}, this gives a 'specific adsorption area' 10^5 cm^2 g^{-1}. In the case of a microporous material (for example zeolites) an average value for the specific adsorption area is 1.5×10^7 cm^2 g^{-1}, a factor 150 greater than for non-porous grains. This enhancement is interpreted as resulting from a volume-filling effect. The consequences of these properties for the formation of hydrogen molecules in interstellar space and for the retentive siting of noble gases in meteorites are examined below.

The condition for efficient H_2 formation on a grain surface is that the residence time of an adsorbed atom exceeds the mean time interval between successive arrivals of H atoms. This gives a maximum grain temperature

$$T_m = \frac{q}{\ln(\alpha \langle v \rangle n_H \sigma \tau_0)}$$

where q is the binding energy (Kelvin) of an H atom, α is the sticking coefficient, $\langle v \rangle$ is the mean H atom velocity, σ is the grain cross-sectional area, and τ_0 is a characteristic desorption lifetime. Early estimates[5] including the effect of zero-point

energy in the adsorption energy, with $q = 200$ K, yielded $T_m \simeq 6$ K for typical interstellar conditions. This value of grain temperature is unacceptably low. Even the later calculations of Hollenbach and Salpeter[6] which give $q \sim 400$ K (for hydrogen adsorbed on water ice) and $T_m \sim 12$ K allow molecular formation to occur only in clouds where dust shielding is significant. To increase T_m they proposed sites of greater binding on the grain, because of the presence of impurities and dislocations, with $q \sim 2,000$ K. For the limited number of these sites they chose, T_m increased to 40 K. Microporosity can, however, lead to an increase in q at all sites in all micropores. An increase by a factor of ~ 5 gives maximum grain temperatures of ~ 30 K. Even higher values of T_m are likely since the value $\tau_0 = 6 \times 10^{-13}$ s used in earlier calculations is based on the Frenkel theory of adsorption for non-porous surfaces. An increase of τ_0 by several orders of magnitude, likely for porous materials, would lead to $T_m \gg 30$ K. No dust shielding is then required, and H_2 recombination could take place on relatively 'hot' grains, even in intercloud regions. Such an effect could be important in accounting for recent Copernicus observations[7].

Porous grains will have a major role in the origin of primordial noble gases in meteorites. An outstanding problem concerning the origin of noble gases in meteorites is the enormously large nebular pressures needed to account for the observed abundances in carbonaceous chondrites, if one assumes equilibrium solubility models[8,9]. Using the experimental data of solubilities in magnetite, the pressures needed to obtain the observed amounts of rare gases are 5–8 orders of magnitude larger[10] than might be reasonably estimated[11]. To overcome this difficulty it has been hypothesised[8] that the equilibrium solubility of noble gases are 5–8 orders of magnitude larger in the minerals where these gases are found than in magnetite. Alternatively, it has been proposed that the noble gases may be trapped by physical adsorption, the need for a hypothetical increase in solubility thus being avoided. The nebular pressures required for such adsorption are marginally plausible[12] within the framework of detailed numerical models for the condensation of the solar nebula[11]. Furthermore, the observed elemental pattern of the noble gases is well reproduced by an adsorption process.

This model, however, based on measurements made on the Allende meteorite, suffers two major drawbacks[10]. Extensive heating[13] and etching[14] experiments on several meteorites indicate that the associated gases are firmly bound, and seem to be uniformly distributed throughout the host crystal. These facts may be taken to imply that the role of adsorption in the conventional sense is minimal.

The presence of micropores will alter this picture. The retentivity will increase enormously from an increase in the physisorption energy. Further, the micropores will allow the gases to fill the entire volume of grains as opposed to some specific surfaces alone. Of course, the evidence gathered so far from meteorites indicates merely the existence of pores. The spectrum of the radii of the pores has not yet been determined. The above physical arguments strongly suggest, however, that the minerals containing the noble gases will be highly microporous. An experimental determination of the degree of microporosity of chondrites is thus timely and highly desirable.

Photon correlation study of stellar scintillation

DURING the past decade photomultiplier-tube technology and signal processing using integrated circuits have progressed to the point at which the analysis of fluctuating light signals can now be carried out digitally, in real time, with accuracy close to the theoretical limit. These 'photon correlation' techniques have so far found their main application in laser light-scattering spectroscopy[1] and laser doppler velocimetry[2]. The techniques need not, however, be limited to applications involving lasers and can be used for the analysis of fluctuating optical signals of any origin (provided the fluctuation time is $\geq 10^{-8}$ s). Here we report a preliminary study of the statistical and temporal correlation properties of stellar scintillation, taking advantage of the fast response time and high sensitivity of equipment now standard for laser light-scattering applications.

The twinkling of stars is, of course, a phenomenon of long standing interest and a continuing source of controversy. It is caused by the presence of fluctuations in the refractive index of the Earth's atmosphere, but the exact nature and role of these fluctuations seems to be in some dispute[3,4]. The twinkling phenomenon is associated with a fluctuation in amplitude, or scintillation, of the optical intensity incident on the eye. This is a potential source of information and can be used as a remote probe of the atmosphere just as radio-star scintillation has been used to investigate the ionosphere[5]. There is indeed a good deal of current interest in this aspect of the phenomenon[6,7]. Unfortunately, it is also a form of noise which may limit the resolution of astronomical telescopes. The current development of stellar speckle interferometry[8] as a means of overcoming conditions of bad seeing therefore provides further motivation for a quantitative characterisation and understanding of stellar scintillation.

Observations were made in late January, 1976, at RSRE, Malvern (52°8'N, 2°20'W). The results on Sirius (α Canis Majoris) reported here were obtained between 2030 and 2200

on January 20 with the star coordinates near 165° azimuth and 21° elevation. Qualitatively similar results were obtained with Vega (α Lyr) during the same period. A blustery westerly airstream covered the region at this time with wind speeds of the order of 10–15 knots near the ground. An ITT FW130 (S20) photomultiplier, preceded by an 18.5-cm focal length telephoto lens and a filter centred at 443 nm with bandwidth 5nm and 20% transmission, was mounted about 40 feet above the ground on a radar dish programmed to track the star. The star was imaged with $f/22$ optics (0.84-cm diameter aperture) on to a field stop of diameter 1 mm; this was followed by a dispersing lens which distributed the received light over the photocathode of the detector. The photomultiplier output was thus a measure of the light intensity falling on an area of about 0.55 cm². Photon detection rates were typically greater than 2.5×10^4 s^{-1} when the star was in the field of view and of the order of 10^3 s^{-1} when it was not, made up of 10^2 s^{-1} room temperature dark count and 9×10^2 s^{-1} sky background. The optical assembly, including telephoto lens, viewing system, phototube and amplifier–discriminator circuitry, and the digital correlator used to measure photon statistics and correlations, were standard commercial items (Malvern Instruments, UK). For correlation measurements the correlator was operated in the single-scaled mode[9], which provided a direct measurement of the normalised intensity correlation function, $g^{(2)}(\tau)(= \langle I(0)I(\tau)\rangle/\langle I\rangle^2$ where I is the light intensity and τ the delay time), whatever the statistics of I.

Fig. 2 Probability distribution of photon detections. Experimental points would lie on the straight line if the received light field were Gaussian distributed with the same mean of about 1 count per 40-μs sample time.
Figure 1a shows a composite correlation function obtained from several measurements of 1–2-min duration with sampling times varying from 20 to 200 μs. A band roughly 2 s.d. wide indicates run-to-run variations which arise from both finite counting times and non-stationary atmospheric conditions. The normalised contrast

$$\lim_{\tau \to 0} g^{(2)}(\tau) - 1$$

corrected for background, is about 1.9, significantly greater than the value of unity expected for Gaussian light. The non-Gaussian nature of the fluctuations is also reflected in the higher-order intensity moments (Table 1) and the photon-counting probability distribution (Fig. 2). A considerably reduced contrast of ~ 0.42 was observed, however, when the colour filter was removed (Fig. 1b). The width at half-height of the correlation function is about 10^{-3} s implying a characteristic fluctuation time much shorter than the commonly accepted value for the response time of the eye. Taking this to be of order 1/25 s, however, a r.m.s. contrast of about 10% after temporal integration of the whole visible spectrum is indicated or 20% if integration is restricted to a 5-nm band. Since the eye perceives fluctuations in colour, the latter figure would seem to be appropriate for comparison and not inconsistent with visual observations, although physiological effects due to image motion on the retina cannot be ruled out[10].

To our knowledge non-Gaussian fluctuations giving contrast in excess of unity have not been observed in any previous measurements of stellar scintillation[11], probably because in earlier experiments averaging of the intensity pattern occurred through the use of large apertures, insufficiently narrow filters or simply slow response time instrumentation. High contrast intensity patterns are known to be produced in certain conditions when an infinite plane wave is scattered by a random phase screen or inhomogeneous medium[12]. In particular, a random-phase screen characterised by a single length scale and introducing path differences greater than about one-third of a wavelength produces large intensity fluctuations in the region of focusing determined by the lens-like behaviour of individual refractive index inhomogeneities[13]. Our results seem to be consistent with recent theoretical predictions based on this interpretation of the origin of stellar scintillation[14]. The phenomenon of focusing, however, is highly model dependent[12,15] and further experiments are essential if the role of the various turbulent layer structures present in the atmosphere is to be fully elucidated.

Finally, it is worth noting that the shadow patterns observed in the receiving plane of large aperture telescopes[16] are, in conditions of high contrast, probably smeared-out caustics. The presence of many of these within the aperture would indicate that light from many (strong) atmospheric scatterers was entering the optical system leading to near-Gaussian speckle in the image[8].

We thank Flt Lt R. C. Perry (RAF) and his staff for assistance in operating the radar dish, and members of the Applied Optics Section at Imperial College and Dr H. E. Butler of the Royal Observatory, Edinburgh, for discussions.

Q in cosmology

THE following example in classical mechanics yields the key equations of relativistic cosmology, including the new equations by Harrison[1]. The argument given here develops that of an earlier note[2].

A set of n gravitating particles of masses m_i are at positions $r_i(0) = a_i$ relative to a fixed origin at the time $t = 0$, when an explosion gives a radial motion $r_i(t) = R(t)a_i$ to all the particles. The scale factor R is the same for all the particles. The kinetic energy of the system at time t is a sum of terms of the type $\frac{1}{2}m_iv_i^2$, and the gravitational potential energy is a sum of terms of the form ($|a_i - a_j| \equiv a_{ij}$)

$$-G\frac{m_i m_j}{r_{ij}(t)} = -G\frac{m_i m_j}{a_{ij}}\frac{1}{R(t)}$$

Accordingly, the energy equation of the system is

$$E = A\dot{R}^2 - B/R, \quad A \equiv \frac{1}{2}\Sigma_i m_i a_i^2, \quad B \equiv \frac{G}{2}\sum_{i \neq j}\frac{m_i m_j}{a_{ij}} \quad (1)$$

To attain a formal analogy with relativistic cosmology, write

$$E/A \equiv -kc^2, \quad B/A \equiv C,$$

and add a cosmological energy term $A\lambda R^2/3$. This gives the following energy equation and its first and second time derivatives

$$\frac{\lambda}{3} = H^2 + \frac{kc^2}{R^2} - \frac{C}{R^3} \qquad (H \equiv \dot{R}/R) \quad (2)$$

$$\frac{\lambda}{3} = \frac{C}{2R^3} - qH^2 \qquad (q \equiv -\ddot{R}R/\dot{R}^2) \quad (3)$$

$$\frac{\lambda}{3} = QH^2 - \frac{C}{R^3} \qquad (Q \equiv R^2\dddot{R}/\dot{R}^3) \quad (4)$$

The importance of the Q parameter has already been noted[1]. One obtains the basic cosmological differential equation in two forms which are independent of the experimentally little known parameter λ, by equating equations (2) and (3) or by equating (2) and (4)

$$\frac{kc^2}{R^2} = \frac{3C}{2R^3} - (q+1)H^2 \quad (5)$$

$$\frac{kc^2}{R^2} = (Q-1)H^2 \quad (6)$$

Adding twice (3) to (4) and taking (3) from (4):

$$\lambda = (Q-2q)H^2, \frac{3C}{2R} = (Q+q)H^2 \quad (7,8)$$

In a Newtonian context, the system is ever expanding if E is positive; that is, if k is negative. By equation (6), the appropriate condition is $Q < 1$, and for $\lambda = 0$ models, it is equivalent to $q < \frac{1}{2}$ (equation (7)). The inequalities are reversed if the system is to collapse again. Note that only if one puts (ρ is the mass density)

$$C = \frac{8\pi}{3}G\rho R^3 \quad (9)$$

do these become the equations given by Harrison[1]. The simplicity of the example given here is illuminating: the role of q, which determines whether a ($\lambda = 0$)-model is closed or open, can clearly be taken over by Q if $\lambda \neq 0$. A continuous distribution of gravitating matter, which is needed to obtain equation (9) in general relativity, and which was used in ref. 1, is clearly not needed here. A discrete distribution of galaxies with sufficient symmetry to ensure the continued validity of Hubble's Law is all that is required. It is to be emphasised that in Newtonian cosmology it is possible to give discussions of interacting particles and discrete matter distributions which give Hubble's Law, though the corresponding general relativistic problems remain unsolved.

This possibility has been noted already[2,3], but no example has been given before. The simplest distribution to verify this possibility is a set of eight galaxies, each of mass m, on the vertices of a cube of side $2a_0$, which are given velocities, v, radially away from the centre of the cube. Because of the seven other galaxies each galaxy is then subject to a deceleration in the direction of the centre. Its magnitude is

$$\frac{D}{2a(t)^2}, \quad D \equiv \left[1 + \frac{\sqrt{2}}{2} + \frac{\sqrt{3}}{9}\right]\frac{Gm}{2}$$

where $2a(t)$ is the side of the cube at time t. If the escape velocity $v_{esc} = \sqrt{(D/a_0)}$ has been exceeded, the Hubble parameter is

$$\frac{\theta^3(1+w^2)^{\frac{1}{2}}}{Dw^3}, \qquad \theta \equiv (v^2 - v_{esc}^2)^{\frac{1}{2}}$$

$$w \equiv \theta\sqrt{[a(t)/D]}.$$

Essentially, a topic for so far undiscovered theorems in Newtonian physics is raised here: the classification of (usually unstable) particle configurations which, for a given interaction, are consistent with a Hubble type expansion; and expressions for the Hubble parameter should also be found in each case.

Anomalous M_1 tide at Lagos

I HAVE recently described[1] the phenomenal appearance in the seas off western Europe of a tidal component with a period of exactly one mean lunar day, namely the "M_1 tide". Although only a few mm in amplitude, it is about ten times larger than one would expect from comparison with ordinary diurnal tides, and suggests a resonant response of

part of the Atlantic Ocean to forcing functions which are symmetrical with respect to the Equator. The forcing function for the ordinary diurnal tides is antisymmetric, and its components are relatively suppressed, enhancing the appearance of M_1 in this sea area.

Most of the places for which I showed evidence of an enhanced M_1 tide, however, were in the shelf seas surrounding the British Isles. The one notable exception was Terceira (Azores), where the results were somewhat marginal. It might therefore have been suggested that the phenomenon is not really oceanic but is confined to the north-west European shelf, although I gave some reasons why this seemed unlikely. I now describe results which confirm the oceanic scale of this effect.

Resolution of the true M_1 tide requires at least 5 yr, and preferably 9 yr of data. A tidal record of more than 9 yr duration has been obtained from Lagos on the south Portuguese coast (near Cape St Vincent; $37°06'N, 8°40'W$), through the cooperation of the Instituto Geografico e Cadastral at Lisbon. The tide gauge, being maintained for geodetic purposes, is excellent in quality, and analysis of the records shows them to have very low noise level and a virtual absence of nonlinear effects. The true M_1 tide stands out clearly from its spectral background, with an amplitude of 5 mm and Greenwich phase lag G of $245°$, representing an admittance to the normalised generating function[2] of 1.23. By contrast, the major component of the ordinary diurnal tide, at a frequency close to 1 cycle per lunar day but actually $1/8.85$ cycles yr^{-1} greater than that of M_1, has amplitude 4 mm, $G=5°$, representing an admittance to its generating function of only 0.19. Lagos is far enough from Britain not to be affected by resonances in British shelf seas, should they exist, so a significant part of the north-eastern Atlantic must be involved. Also, a definite northwards progression of phases across the eastern oceanic shelf edge now emerges, as seen by the following list of phase lags G for the M_1 tide: Lagos, $245°$; Brest, $268°$; Scilly, $276°$; Malin, $312°$; Stornoway, $308°$; Lerwick, $330°$.

Apart from a slight anomaly at Stornoway, the trend of the phases is in keeping with the progression of the normal mode of the Atlantic/Indian ocean system at 23.5-h period, computed by Platzman[3], which I cited earlier[1] as an explanation of the M_1 phenomenon. Platzman's mode progresses in phase by $45°$ roughly between the positions of Lisbon and the Faeroes. G for Terceira is $275°$, about the same as Scilly, indicating a cotidal line stretching south-west from Scilly. This, together with the reduced amplitude at Terceira, again supports Platzman's modal diagram.

Diachronism in Old World alluvial sequences

THE diachronism of an environmental change—that is, the extent to which its age varies with location—is a useful clue to its origin[1]. In the case of alluvial sequences, the time taken for filling and trenching to work their way through a drainage basin is likely to obscure chronological differences between basins unless they are sufficiently distant from each other for any regional trend to become apparent. I report here ^{14}C dates for alluvial units in south-eastern Spain, and suggest that they are consistent with the effects of latitudinally diachronous

Fig. 1 Location of Spanish sampling sites discussed in text.

deposition throughout the Mediterranean Basin and Near East.

The Mundo is a tributary of the Segura[2], which drains into the Mediterranean south of Alicante. Three Quaternary valley deposits can be identified in the reaches shown in Fig. 1. The oldest, for which I propose the name Ayna Tufa, has a maximum thickness of 17 m above Ayna, where it overlies Mesozoic limestone and grades upstream into a well stratified marl. The tufas and marls are surmounted by a deposit which takes the form of cemented scree at Ayna and of a valley fill below Ayna and in many other valleys in the area. This unit, for which the name Elche Formation is proposed, attains its maximum observed thickness of 11 m in the Rambla de Dilar; it is generally characterised by subangular gravel in a red, sandy matrix and includes horizons strongly cemented by calcium carbonate. Channels cut into the Elche sediments have been partially filled, to a maximum observed depth of 2.5 m, by a well bedded deposit composed of silts, sands and gravels for which the name Lietor Alluvium is proposed. This unit is at present undergoing trenching.

A more complex Quaternary succession has been reported from the central and southern parts of the Province of Alicante[3] but secure ^{14}C dates are still not available for it. Elsewhere in south-eastern Spain the dating of continental deposits is based largely on their relationship to fossil beaches whose age is in dispute or on correlation with other areas[4,5]. Four ^{14}C dates were obtained during the present study (Table 1). The first was on charcoal from a slightly disturbed hearth near the base of the Elche Formation south of Molinicos (JCD 2). It is worth adding that at Ayna the cemented scree yielded a single Palaeolithic artefact, and that concentrations of Mesolithic material were found on the surface of the Elche Formation at various localities near La Dehesa. The Lietor Alluvium supplied datable charcoal in a gravel pit near Liétor (DW 11), in the Rambla de Dilar, where it forms a terrace remnant (LT 1), and south of Molinicos, where it is represented by colluvium overlying the Elche Formation (JCD 1). The three dates tally satisfactorily, and indicate an age of about 700 yr for the mid-point in aggradation.

A threefold post-Tertiary valley sequence similar to that outlined here has been reported from numerous valleys in other parts of the Mediterranean Basin and in the Near East[6,7] and also in central Périgord[8]. It has been suggested[6] that the tufa reflects greater spring discharges than those of today, that the older of the alluvial fills points to active frost weathering in the uplands coupled with the incidence of intense but short-lived and infrequent rains comparable to those now prevailing at lower latitudes, and that accumulation of the younger fill was in response to a temporary southward shift in the depression belts of Europe. The onset of the last of the three episodes

Table 1 ^{14}C dating of rock units

Rock unit	Sample no.	Laboratory no.	Grid reference	Location	Age (yr b.p.)	$^{13}C \cdot {}^{12}C$ rel. PDB (‰)	Material	Remarks
Elche Formation	JCD 2	SRR-730	7274 × 4317	2°14′22″W 38°27′30″N	39,735 + 1,190 − 1,035	−22.2	Charcoal	At depth of 9 m in 10-m section
Lietor Alluvium	LT 1	SRR-726	7453 × 4363	20°0′46″W	819 ± 35	−23.2	Charcoal	At depth of 1.5 m in 2.5-m section
		SRR-727		38°30′39″N	853 ± 50	−23.4	Charcoal	Repeat analysis
Lietor Alluvium	DW 11	SRR-728	7492 × 4439	1°58′12″W 38°34′43″N	780 ± 110	−24.7	Charcoal	At depth of 1.5 m in 2.5-m section
Lietor Alluvium	JCD 1	SRR-729	7274 × 4318	2°14′22″W 38°27′30″N	419 ± 65	−25.0	Charcoal	At depth of 1 m in 3-m section

varies by up to 500 yr according to location. This has been cited in support of the view that aggradation stemmed from man-induced soil erosion[9], but a preliminary plot against latitude of the ^{14}C dates then available for the deposit indicated a latitudinal decrease in its age which seemed to favour the 'cyclonic' explanation[10].

Figure 2 extends this approach to the other two units. It incorporates the Spanish material and all the other ^{14}C dates whose attribution is certain, as well as limiting archaeological ages derived from historical sites or from excavated material locally calibrated with the help of radiocarbon dating. Granted that the number of points remains small, that they include some (notably those on tufa) which are open to challenge, and that no correction has been made for altitude or other possible

Fig. 2 Plot of age against latitude and provenance of ^{14}C dates for the three deposits reviewed. The upper stippled zone includes the dates for the younger alluvial fill, the lower stippled zone those for the older fill, the blank area between them those for the intervening erosional phase, and the blank triangle at the base those for the tufa. The only dates which do not conform to this scheme are the two from the Dordogne (⊡) within the lower stippled zone, as they are on tufa, but this tallies with field evidence for overlap between tufaceous and alluvial deposition in that area[8]. Archaeological ages (—) include some that immediately predate (⊥) or postdate (⊤) the younger fill. Data from this article and from refs 6–9 and 12.

distorting factors, there is some indication of a northward lag in the transition from tufaceous to alluvial deposition, and of a southward lag in the onset of the second alluvial phase. The graphs also suggest that in both instances aggradation terminated more abruptly than it began, just as the trenching of individual valley fills often progresses more rapidly than does their accumulation[11]. Figure 2 could be taken to imply that the climatic conditions responsible for the older of the alluvial fills emanated from lower latitudes, whereas those that produced the younger fills stemmed from higher latitudes, both inferences being in accord with the interpretations prompted by the field evidence. It remains to be seen whether additonal ^{14}C dates will support the graphs so that their gradients can be used to test palaeo-climatic hypotheses with some confidence.

Effect of mineral precipitation on isotopic composition and ^{14}C dating of groundwater

I PRESENT here a method for determining the combined effects of concurrent mineral precipitation and dissolution on the carbon isotope composition of groundwater. The results are applied to the 'adjustment problem' in the ^{14}C dating of groundwater, and are illustrated using published data from the London Basin chalk aquifer. Some ^{14}C ages are changed by more than 10,000 yr.

'Raw' ^{14}C data from groundwaters must be adjusted to allow for dilution attributable to the dissolution of bedrock

carbonate which contains no ^{14}C. Either stable isotope measurements or conventional geochemical measurements may be used to determine the adjustment factor. In both cases 'initial' (that is, at the start of conditions which are closed to carbon dioxide) values of either ^{13}C content (δ^{13}C) or total dissolved inorganic carbon molality (mC) must be known[1]. These initial values are often difficult to estimate. In addition, even adjusted ages are subject to errors arising from various forms of contamination within the aquifer[2]. Nevertheless, provided the aquifer geochemistry is well understood, reasonably reliable ages can be determined.

One important and relatively common process has either not been considered, or been considered inadequately, in past studies of carbon isotopes in groundwater: the concurrent dissolution and precipitation of two minerals (that is, incongruent dissolution, if both are carbonate minerals). Because of isotopic fractionation between aqueous phase and solid carbon-containing species, the isotopic composition of any precipitate will differ from that of the parent solution. For dissolution, the dissolved material will generally differ isotopically from the solute. Thus, both precipitation and dissolution must, in general, alter both the stable and unstable isotope composition of a groundwater. This paper presents the first quantitative estimate of the combined effects of these processes.

Let mD be the contribution to changes in mC over a flow-path attributable to dissolution of one mineral, and let mP be the contribution attributable to precipitation of another mineral. Over a flow-path increment the change in mass of ^{13}C carried by the groundwater must balance the net gain attributable to dissolution and loss attributable to precipitation. This mass balance may be expressed mathematically as

$$d(mC\delta^{13}C) \approx \delta^{13}C_s d(mD) - \delta^{13}C_p d(mP)$$

where 's' and 'p' denote bedrock and precipitate values. In terms of the fractionation factor between precipitate and solution

$$F = \delta^{13}C_p - \delta^{13}C$$

this becomes

$$mCd(\delta^{13}C) + \delta^{13}Cd(mC) \approx \delta^{13}C_s d(mD) - (\delta^{13}C + F)d(mP)$$

If $\alpha = d(mD)/d(mP)$ is the relative dissolution to precipitation contribution to mC, then, for $\alpha =$ constant and $F =$ constant, and noting that $d(mC) = d(mD) - d(mP)$, the above can be integrated to give

$$\delta^{13}C - \delta^{13}C_s \approx X(\delta^{13}C_0 - \delta^{13}C_s) + F(X-1)/\alpha \qquad (1)$$

where

$$X = \left\{ \frac{mC}{mC_0} \right\}^{\alpha/(1-\alpha)} , \alpha \neq 1$$

$$X = e^{-mP/mC_0} , \alpha = 1$$

here, '0' denotes the value at the commencement of concurrent dissolution and precipitation. This would normally be preceded by a dissolution-only period. In equation (1), $X(\delta^{13}C_0 - \delta^{13}C_s)$ is the contribution attributable to precipitation and dissolution ignoring fractionation, and $F(X-1)/\alpha$ is the fractionation effect. As α tends to infinity (that is, dissolution dominates) this term becomes small and the usual dissolution-only result obtains.

For ^{14}C, the corresponding relationship is

$$A \approx A_0 X \qquad (2)$$
Fig. 1 Comparison of groundwater ages before and after adjustment for the effects of concurrent mineral precipitation and dissolution. Numbers, site numbers used by Smith *et al.*[3,4]; solid circles, data values regarded by Smith *et al.* as having the greatest error margins. For points to the left of the dashed line the precipitation–dissolution adjustment is greater than 10,000 yr.

where A is the activity (in % modern). Detailed derivations of these results will be given elsewhere.

These results are based on the assumptions of constant α and F. Constant α implies constancy of the relative driving forces for dissolution and precipitation. Although made here in the interest of mathematical tractability, I believe that, in the absence of detailed geochemical information from particular aquifers, it is the best possible assumption. The fractionation factor, F, varies considerably with pH and temperature; however, at the relatively high pH values needed to allow concurrent dissolution and precipitation, F is largely independent of these variables and is approximately 2.5‰.

After extensive combined dissolution and precipitation (that is, X tending to zero), equations (1) and (2) show that the isotope concentrations tend to limiting values of $\delta^{13}C_s - (F/\alpha)$ and 0%. Since $F \approx 2.5$‰ this allows $\delta^{13}C$ to approach the bedrock value closely. In addition, ^{14}C activity may become very low independently of groundwater age. As an example, if $\alpha = 1$, $\delta^{13}C_s = 0$‰, and $F = 2.5$‰, the limiting $\delta^{13}C$ is -2.5‰, much higher than expected in the absence of mineral precipitation. This limit corresponds to a steady state where 0‰ carbon is added to the groundwater by dissolution, while 0‰ carbon (that is, the groundwater value plus 2.5‰ fractionation) is being lost at an equal rate by precipitation.

Equation (1) can be used to adjust ^{14}C ages and so give an idea of the magnitude of dissolution–precipitation effects on the ^{14}C dating of groundwaters. Ages adjusted in this way will, necessarily, differ from those obtained using the dissolution-only formula (that is, equation (1) with $F = 0$). The difference will be one half life when $X = F/[F - \alpha(\delta^{13}C_0 - \delta^{13}C_s)]$. Greater differences will occur for smaller values of X (that is, as $\delta^{13}C$ approaches its limiting value). Values of X less than the above correspond to $\delta^{13}C$ values within about 3‰ of the limiting value. Since age errors of one half life (or more) are quite significant, a proper consideration of precipitation effects can be extremely important. As $\delta^{13}C$ approaches its limiting value the adjustment factor becomes increasingly sensitive to small errors in the data and/or the model. Thus, unfortunately,

the uncertainty in the adjustment increases as the magnitude of the adjustment increases.

To illustrate the possible magnitude of this effect I have re-evaluated isotope data from the London Basin chalk aquifer given by Smith et al.[3,4]. These authors state that the anomalously high values of $\delta^{13}C$ observed in this aquifer are most probably attributable to concurrent dissolution and precipitation. In adjusting ^{14}C ages, however, they did not take fractionation effects into account, and used the standard dissolution-only formula. In the London Basin, $\delta^{13}C_s \approx 2.35\%_0$. The chemical evolution of the groundwater seems to be closed-system dissolution (during which $\delta^{13}C$ evolves from a soil-zone value of $-26\%_0$ to around $-13\%_0$) followed by concurrent dissolution and precipitation. The dissolution-only period reduces the ^{14}C activity to around 50%, so that the age may be estimated by

$$t = \frac{5,730}{\log 2} \log \left(\frac{50X}{A_m} \right)$$

where A_m is the measured groundwater activity and X is given (using equation (1) and assuming $\alpha = 1$) by

$$X = \frac{(-\delta^{13}C - 0.15)}{12.85}$$

Figure 1 compares the ages given by Smith et al.[3,4] with ages recalculated using the relationship defined here. The differences are, in some instances very large: more than 10,000 yr in four cases. Adjustments of this magnitude are of considerable importance. In support of these calculations it is reassuring that none of the $\delta^{13}C$ values observed by Smith et al.[3,4] exceeds the limiting value of $-0.15\%_0$ implied by equation (1).

Smith et al.[3] have suggested that some of the London Basin water may be recharge dating from before the last glacial maximum. This suggestion can be re-examined in the light of the revised ages (Fig. 1). After the last glacial maximum, the earliest recharge to the aquifer probably occurred during the first post-glacial warm period around 13,000 yr b.p. Ages in excess of this would confirm the suggestion of Smith et al.[3,4]. Although many ages are substantially younger after readjustment, some of the ages still, indeed, exceed 13,000 yr b.p.; however, in view of the large uncertainties involved in allowing for mineral-precipitation effects, and the proximity of many $\delta^{13}C$ values to the theoretical limiting value (when adjustment uncertainty is greatest), the possibility that all the waters are younger than 13,000 yr b.p. must remain open.

Nevertheless, a direct interpretation of the ages shown in Fig. 1 supports the suggestion of Smith et al.[3,4]. Some of the readjusted groundwater dates do fall within the last glacial maximum period. Since recharge at this time was probably negligible, if these ages are correct then the relevant samples are most probably older waters 'contaminated' by mixing with post-glacial recharge.

In conclusion, mineral precipitation within an aquifer can have a very significant influence on the groundwater isotope geochemistry. Ignoring mineral precipitation, or neglecting isotopic fractionation during precipitation, may lead to estimates of ^{14}C ages which are many thousands of years too old. Stable carbon isotope data may be used to adjust ages, but the largest adjustments are those which are subject to the greatest uncertainty.

I thank R. A. Downing for providing a pre-publication copy of the London Basin results[3,4].

Calcium oxides of high reactivity

A RECENT study of the kinetics of decomposition of calcite ($CaCO_3$) single crystals in vacuo showed that if the reaction was interrupted before completion a 30-μm layer of a poorly crystalline material was present between the undecomposed $CaCO_3$ and a layer of normal polycrystalline CaO^1. It was hypothesised that the material of this 30-μm layer is a metastable form of CaO that transforms irreversibly to the stable polycrystalline oxide when the accumulated strain exceeds a critical level. If so, the free energy of formation of the metastable oxide from the stable oxide must lie in the range between zero and $+31,500 - 21T$ J mol^{-1} and might well lie at the positive end of this range[2]. Such a metastable oxide should be chemically more reactive than the stable oxide. If the hypothesis is true, then the principal product of decomposition in vacuo of calcite particles of diameter < 30 μm should be the metastable oxide. We present here evidence that this inference is correct, and we demonstrate that not only this oxide, but also a highly crystalline oxide which is produced when large calcite crystals are decomposed in vacuo, reacts more vigorously with water than does the product of calcite decomposition in air or nitrogen.

Calcite ground to a powder formed of block-like rather sharp-edged particles with cross sections ranging from 1 to 10 μm (Fig. 1) was decomposed in air or nitrogen in the range of temperatures between 650 °C and 800 °C. The product was composed of particles which had rounded surfaces and neck areas which indicate considerable sintering (Fig. 2). The product gives the diffraction pattern of highly crystalline CaO.

When the same $CaCO_3$ powder was decomposed in vacuo in the range of temperatures between 450 and 750 °C, there was little change in the apparent particle shape from those of the starting material, and little sintering (Fig. 3). It can be calculated from the relative molar volumes of $CaCO_3$ and CaO that the powder particles produced in vacuum decomposition, like the product of $CaCO_3$ single crystals in vacuo[1], must have $> 50\%$ porosity. Unlike the powders decomposed in air or nitrogen, the powders decomposed in vacuo were poorly crystalline, but did show weak diffraction peaks of the normal (NaCl type) CaO structure (Fig. 4). Heights of the (100) peak showed no

Fig. 1 Scanning electron micrograph of $CaCO_3$ powders.

I μm
Fig. 2 Scanning electron micrograph of CaO produced from decomposition of $CaCO_3$ powders in dry nitrogen.

clear systematic dependence on time or temperature of heating (as high as 1,050 °C).

The oxide produced by decomposition of $CaCO_3$ powder in air or nitrogen showed no measurable $Ca(OH)_2$ diffraction peaks when ground for 10 to 15 min in air and gained only 1% in weight when exposed to an atmosphere of water vapour at 140 °C. In contrast, the poorly crystalline oxide produced by decomposition of the same powder *in vacuo* is completely converted to poorly crystalline $Ca(OH)_2$ by grinding in air for 10 min or by 3-min exposure to the water vapour stream at 140 °C. The poorly crystalline hydroxide in turn transforms exothermally to the crystalline hydroxide when heated in air to ~290 °C.

Surprisingly, the product of complete decomposition of single crystals of calcite *in vacuo*, even though a CaO with a degree of crystallinity little different from that of the CaO produced by

Fig. 3 Scanning electron micrograph of CaO produced from decomposition of $CaCO_3$ powder *in vacuo*.
calcite decomposition in air, reacted with water vapour at rates that were not distinguishable by our hydration tests from rates for the poorly crystalline product of vacuum decomposition of $CaCO_3$ powders. This observation shows that the high rates of reactivity of the oxides prepared *in vacuo* are primarily consequences of the high internal surface areas of the block-like products of vacuum decomposition. The blocks produced *in vacuo* have >50% porosity[1], yet the pores are too small to observe at ×30,000. Pore diameters probably average well under 0.01 μm so that solid state diffusion over only short distances is necessary for the hydration reaction. The rounded forms of the oxide particles prepared by decomposition in air must be a consequence of extensive condensed phase diffusion, a process that would probably close the intra-particle pores.

In line with our original hypothesis that the 30-μm layer observed in the interrupted decomposition of a calcite single crystal *in vacuo* is a metastable form of CaO that transforms under sufficient strain to the normal crystalline form, the oxide
Fig. 4 X-ray diffractometer trace (cobalt Kα radiation). *a*, CaO produced from decomposition of $CaCO_3$ *in vacuo*; *b*, CaO produced from decomposition of $CaCO_3$ powders in air.

of this layer is more reactive towards moisture than the other forms here identified. The X-ray peak which in the earlier study[1] was presumed to be a reflection for a metastable oxide is instead the strongest peak of the poorly crystalline hydroxide. The 30-μm oxide layer, after exposure to room temperature air for <1 h, shows only the diffraction peaks for the amorphous hydroxide. In the same conditions, the other products of *in vacuo* decomposition, if not ground, give patterns of either well crystallised or poorly crystalline CaO, as reported above.

Wave power availability in the NE Atlantic

FOLLOWING Salter's[1] proposals for the extraction of energy from sea waves, we are working on the prediction of wave power output from devices situated at favourable coastal sites around the UK. While it is hoped that adequate spectral data from sites closer inshore will become available within the next year or so, the best present data for the North-east Atlantic are from O.W.S. India[2]. We describe here the power available and, on simplified assumptions, the amount that might be extracted by ducks of various diameters. (The Salter 'duck' is a rocking cam-shaped device which is designed to give a high efficiency of energy extraction over a wide frequency band[3].) Confirmation of the validity of the important assumption of additivity of power outputs from wave components of different periods is provided in a separate paper[4].

The power, P, in a sinusoidal wave train in deep water is kTH_{rms}^2 per unit width of wave front, where H_{rms} is the root mean square displacement (that is, the standard deviation) of the water surface, T is the wave period and $k = \rho g^2/4\pi \simeq 7.82$ kW m^{-3} s^{-1}. Thus for a mixed wave train of spectrum dS ($H_{rms}^2 = \int dS$), on linear theory

$$P = k\int T dS = kT_e H_{rms}^2$$

where T_e is called the energy period.

The seasonal joint distributions of T_e and H_{rms} at O.W.S. India are shown in Fig. 1, with contours of P. They are calculated from Hoffman's set of 307 spectra[2] which were selected from a random sample of just over a thousand 10–15 min wave records, taken over the period 1954–67; we weighted each spectrum to restore the correct frequency of occurrence of each band of windspeed in each season. The overall average power is 91 kW m^{-1}.

The predictions given here are for ducks operating with a simple power output limit and (as in the laboratory) relative to a fixed axis. More realistic physical limits on the torque and angular displacement are important for the estimation of the most economic size and characteristics for full-scale ducks, but should not much affect the range of predicted outputs. The related problems of backbone (axis) movement and the directional wave spectrum are more serious; accurate predictions must await laboratory experiments using a less constrained mounting and data on directional spectra at likely wave power sites.

Figure 2 shows the distribution of power by frequency. (For clarity, autumn and spring are omitted; the former would be close to, the latter rather below, the whole year histogram.) Superimposed are efficiency curves for ducks of diameter $d = 6$, 10 and 16 m, scaled up from the experimental curve (for $d = 10$ cm) of Salter, Jeffrey and Taylor[3]. This curve is the result of attempts to optimise performance at low frequencies, so as to minimise the size of duck required for a given sea. The falling off of efficiency at low frequencies is not unexpected, since it cor-

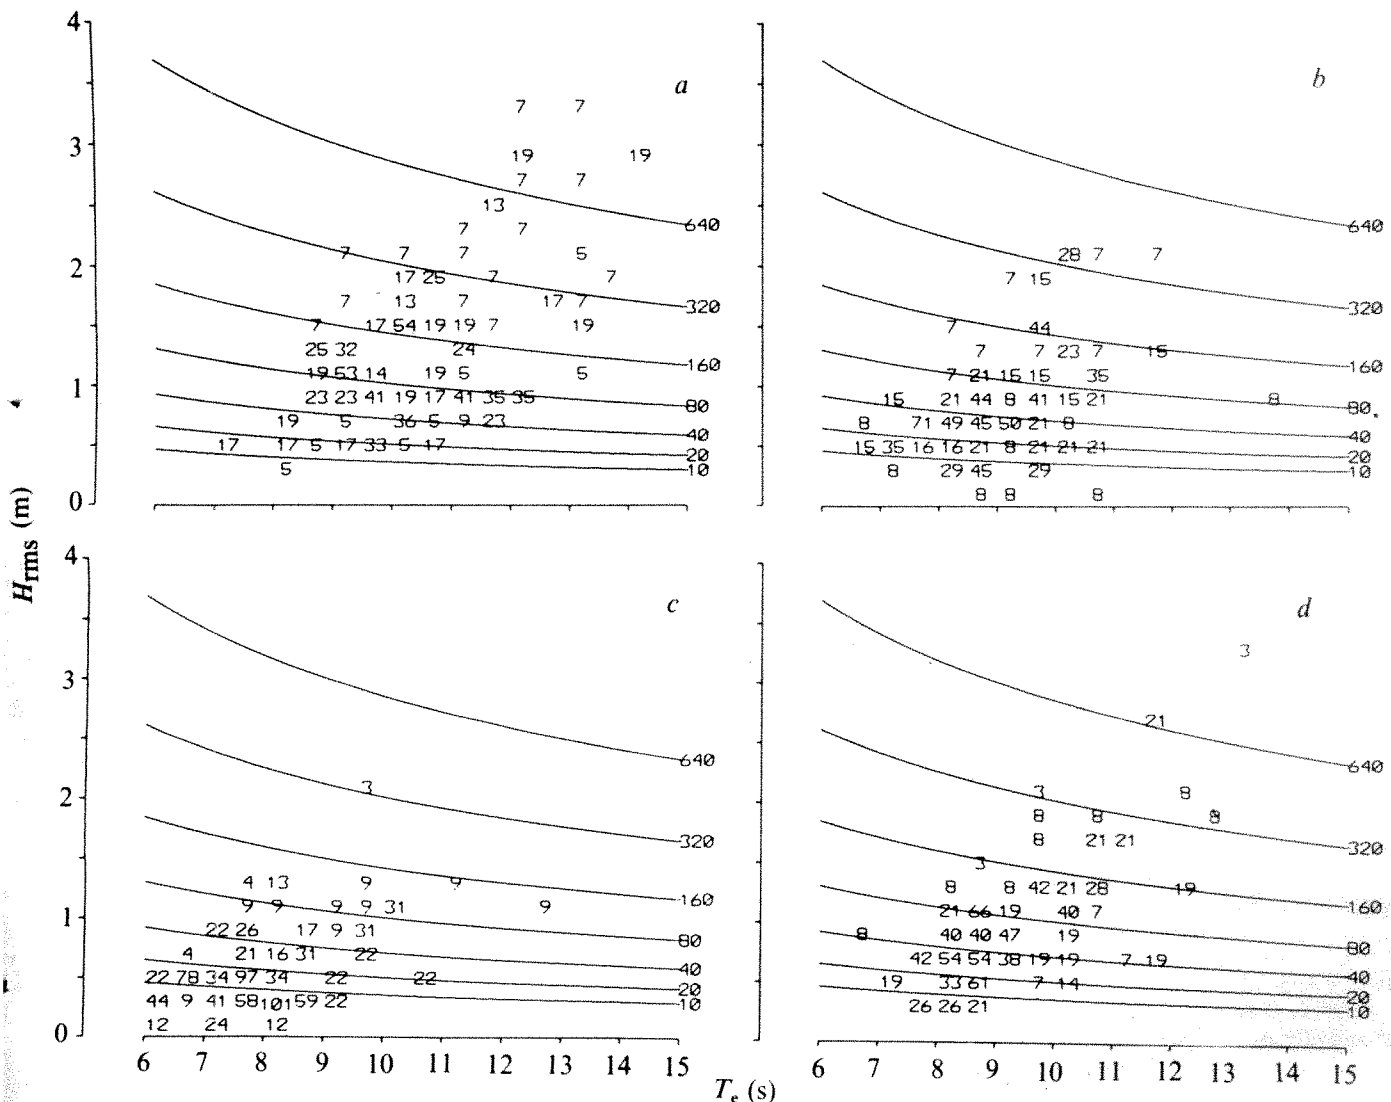
Fig. 1 Frequency of occurrence at O.W.S. India in ‰ of the possible combinations of T_e and H_{rms}, with contours of P in kW m^{-1}. *a*, Winter (Dec-Feb); *b*, spring (Mar-May); *c*, summer (Jun-Aug); *d*, autumn (Sep-Nov).


Fig. 2 Distribution of power by frequency for the whole year (middle histogram), winter (top) and summer (bottom); together with predicted efficiency curves for ducks of 6, 10 and 16 m diameter (dashed lines indicate extrapolation outside experimental range).

responds quite closely to the proportion of energy travelling in the water layer above depth d ($= 1 - \exp\{-2d\omega^2/g\}$).

The average output for a particular duck size and season, if no power limits are imposed, can then be found simply by multiplying the appropriate two curves in Fig. 2 and integrating. This is the power transferred from sea to duck; the conversion to electricity and transmission to a distant load-centre in a hydrodynamically underprivileged area, such as South-east England, can be done with presently available technology with an efficiency of $\sim 60\%$. To investigate the variability of power levels, it is of course necessary to refer to the individual spectra. The proportion of time for which power outputs might exceed any given level is shown in Fig. 3, with the total power available for comparison.

We have investigated the effect on power output calculations of replacing the real sea spectra by two-parameter (H_{rms} and T_e) spectra of standard shape, the shape chosen being that of the Pierson–Moskowitz spectrum[5]

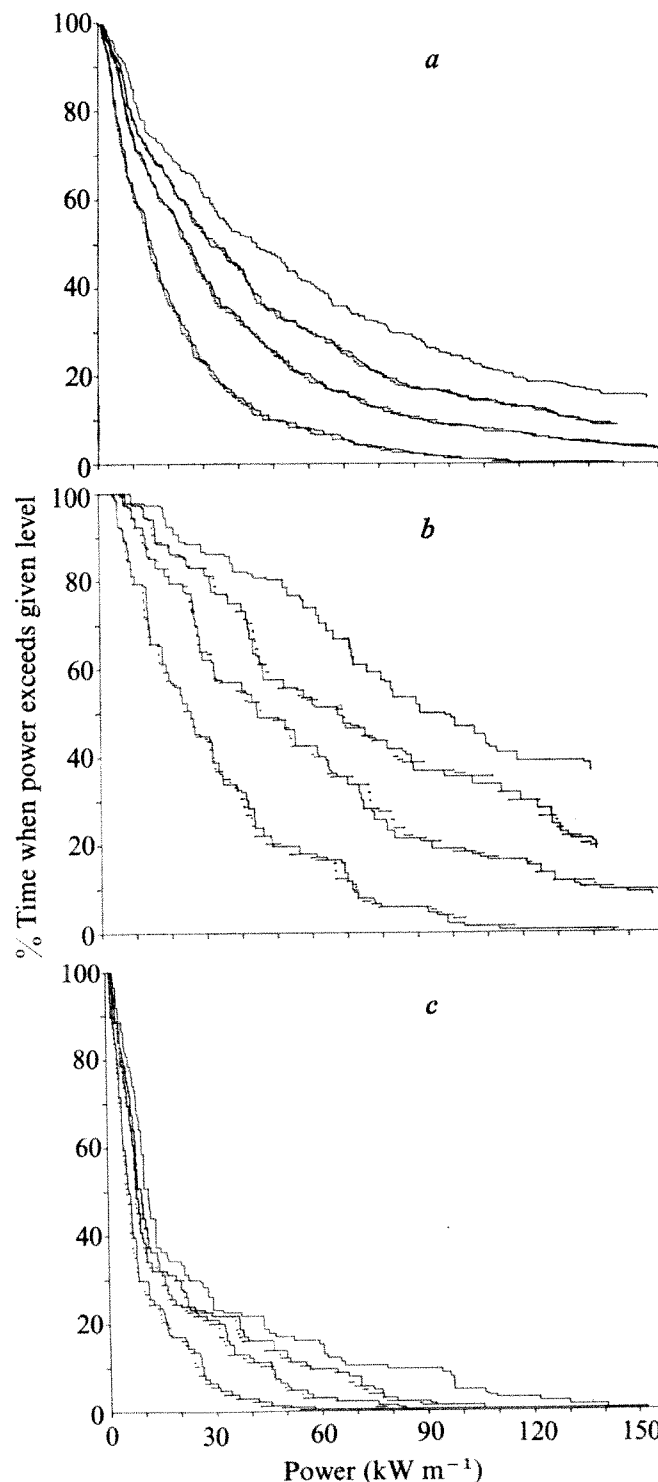
$$\int_0^\omega dS = H_{rms}^2 \exp\{-b(\omega T_e)^{-4}\}$$

where $b \simeq 1,052$ (dimensionless).

This is not only convenient for present computational purposes, but should also greatly facilitate predictions of the effects of physical and torque overloads and the directionality of real seas. This replacement has little effect on the distributions of power input (see Fig. 3, dashed lines), though estimates for individual spectra have s.e. 4.55%. The largest effects on the predicted average output over the range of diameters 6–18 m are -0.5 kW m^{-1} (for $d = 6$ m in the summer) and $+1.5$ kW m^{-1} (for $d = 12$ m in the winter) which may be attributed to real spectra being respectively broader in calm, and narrower in rough conditions than the standard spectra. We conclude that, while further checks are advisable, such standard spectra appear sufficiently accurate for our present approximate predictive purposes. (When directional data become available we intend to extend this investigation to see whether the addition of one further parameter to allow for directional spread yields a similarly adequate description for predicting behaviour of free-floating duck strings in directionally mixed seas.)

Directional problems apart, there are three limitations on output which we have not considered so far: physical (swept-volume), torque and transmission limits. Because of the high costs of transmission lines[6] the last of these is probably the most critical, though swept-volume overload limits will be important for ducks of diameter < 10 m.

The mean power available when simple power output limits

Fig. 3 The proportion of time for which each power level is exceeded for: *a*, whole year; *b*, winter and *c*, summer. In each case the top curve refers to the total power available; the other solid curves, in descending order, to predicted power output from ducks of 16, 10 and 6 m diameter. The dashed curves (verticals omitted) show the effect, for each of these three cases, of replacing real spectral data by two-parameter standard spectra (see text).


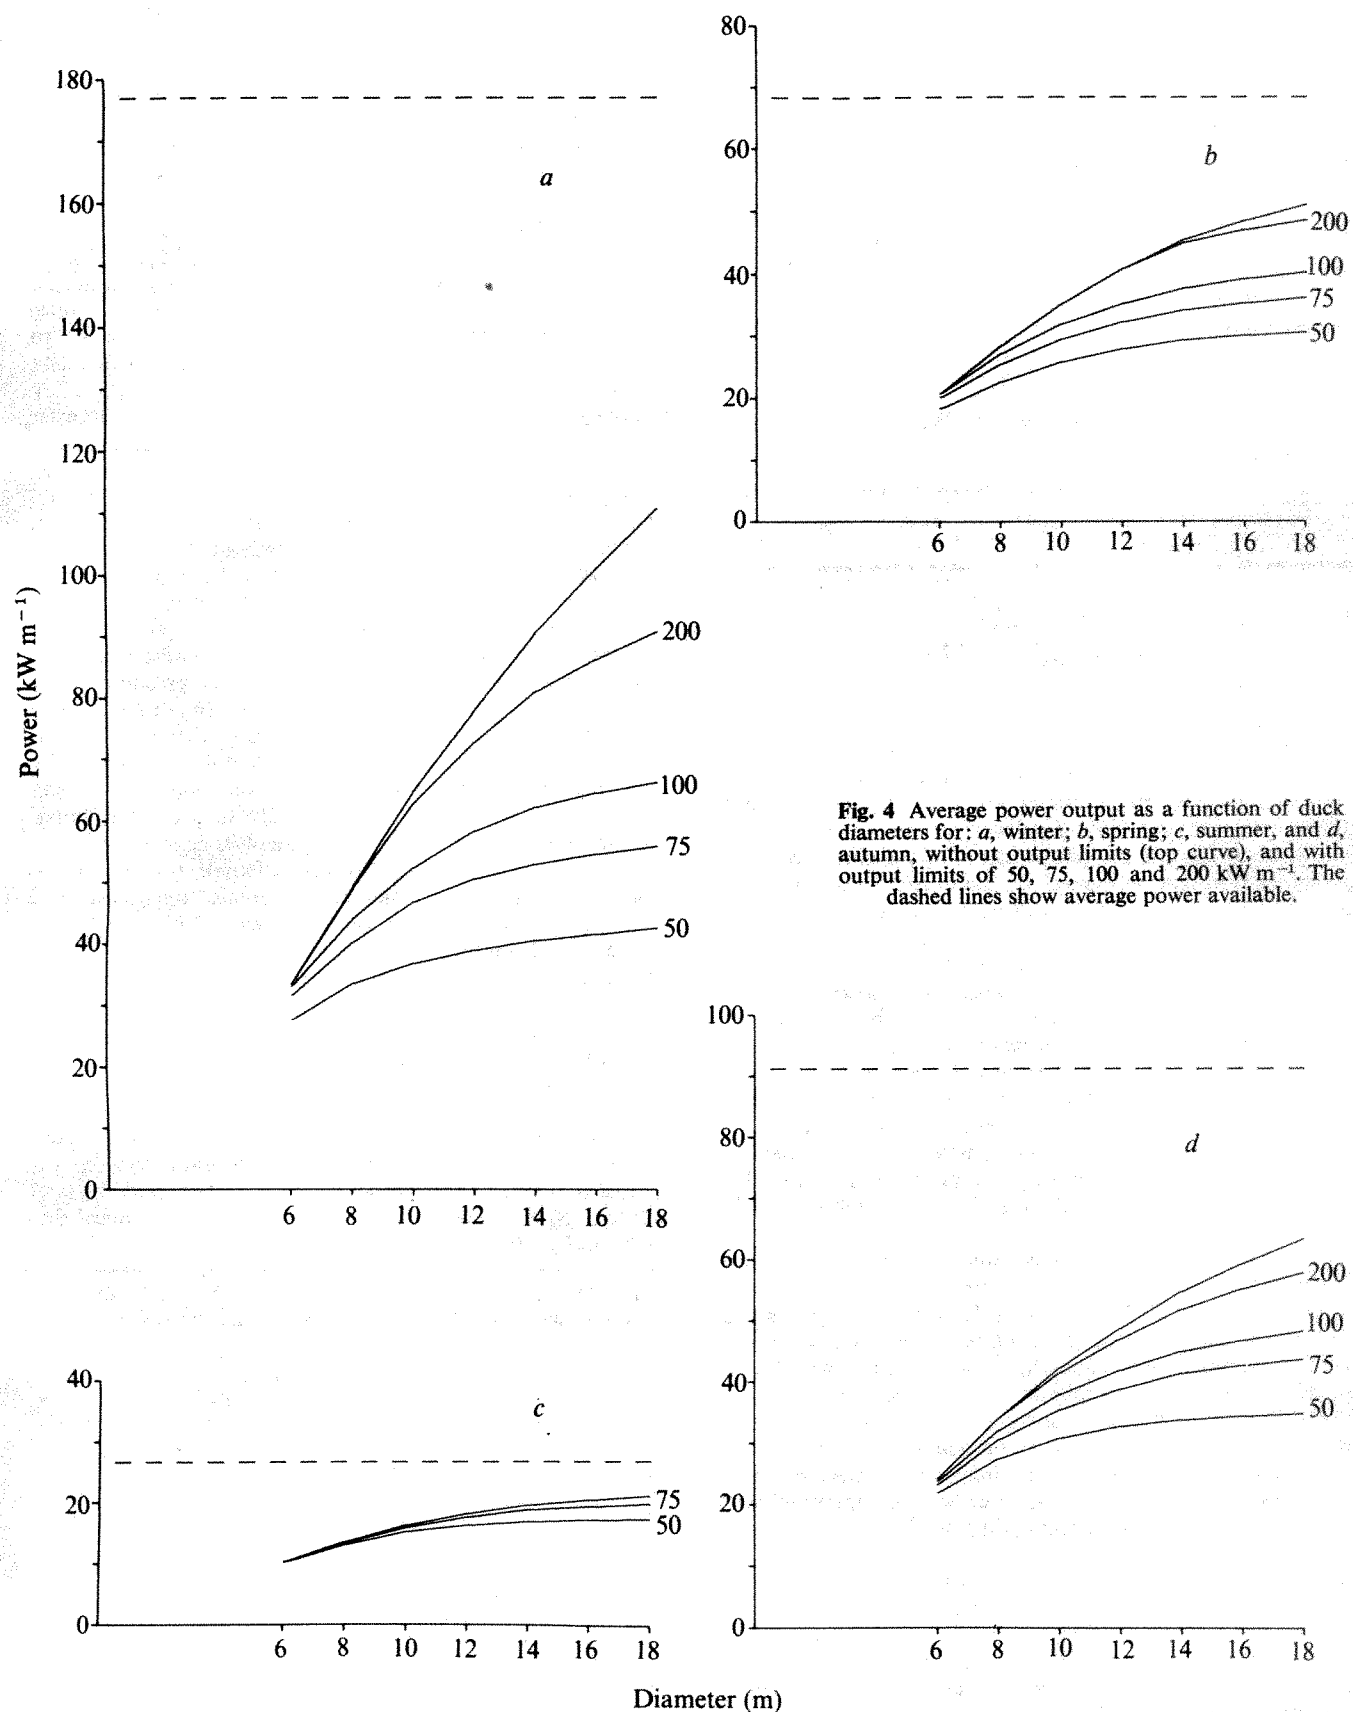


Fig. 4 Average power output as a function of duck diameters for: *a*, winter; *b*, spring; *c*, summer, and *d*, autumn, without output limits (top curve), and with output limits of 50, 75, 100 and 200 kW m^{-1}. The dashed lines show average power available.

are imposed is easily calculable as the area under the relevant curve of Fig. 3 to the left of the desired limit. This is plotted as a function of duck diameter in Fig. 4. As might be expected, the effect of such limits is more severe in winter. Even then the

lowest (50 kW m^{-1}) limit considered gives a substantially higher load factor ($\sim 80\%$ for $d \geq 12$ m), a further reason for preferring a relatively low rated transmission line, rather than going for maximum average output.

Male emigration and female transfer in wild mountain gorilla

IN many group-living primates, males leave their natal group and transfer to other groups far more commonly than do females (for example, refs 1–4). For only one species—the chimpanzee—is there good evidence that females leave their natal group and transfer more commonly than do males[5,6], but little information has been available on the movements in and out of gorilla groups. The structure of the gorilla population in the Virunga Volcanoes of Zaire and Rwanda[7,8] and elsewhere[9] indicates that males at least leave their natal group: there are a number of lone males; and many groups contain only one fully adult male, but a number of adult females. Schaller[9] implied that males transferred between groups more often than did females. The few data in ref. 10 indicate, however, that only females transfer between groups, although both males and females leave groups. Incorporating data for 8.5 yr from the Karisoke Research Centre in the Virunga Volcanoes (ref. 10 and unpublished results), this paper provides the first extensive evidence that both male and female gorillas leave their natal group, although some sons may remain; that males that leave initially travel alone; and that only females transfer.

Groups and lone males will be called 'units'. A distinction must be made between short 'visits' by animals to other units and longer 'transfers'. A 'transfer' is defined as a stay of more than 1 d with the new unit. Males mature when about 11 yr old, their first recorded emigrations being at about this age (Table 1a). Males that did not emigrate were the leading males or animals that were probably some of their sons (Table 1b). Leader males tended to inhibit young males from mating, and competition for oestrous females may be a cause of male emigration. Young males that meet stiff competition will probably leave; those that do not will probably stay, and these are likely to be the sons of ageing leaders. One such male took over leadership of the group when his father died. Such inheritance of leadership may be a pattern common to most groups.

Females become mature at about 8 yr old, and also tended to leave the group at about the age of maturity; they tended to leave before giving birth (Table 2a), as has been reported for chimpanzees[6]. In contrast to males, it seems that nearly all females eventually leave their natal group. Because females transfer between groups, however, for only the four youngest females in Table 2 can we be sure that the group in which they were first seen was their natal group.

The one female that remained in her natal group (Table 2b)

produced an offspring, probably sired by her own father, or by a male who was probably her half-brother. No multi-parous females with living offspring emigrated from the group in which they were first observed (Table 2b).

Four males were intermittently observed for 2–5 yr after they first emigrated out of the study groups. None transferred and all spent most of their time alone. Also, no male transferred into any of the study groups. It seems that males that leave their natal group become successful breeders, not by transferring and not by ousting established group leaders (as do langur males[11,12]), but by attracting more than one female to form a new group. A male and single female seem not to be a viable breeding unit.

Females that emigrate transfer almost immediately to other units (as reported for chimpanzees by Kawanaka and Nishida[5]), and they tend to transfer more than once (Table 2a). The length of stay with one unit before the next transfer ranged from 3 d to 3 yr 5 months, with a median of 3 months ($n = 13$). Initial transfers were to units with ranges overlapping those of the group in which the female was first observed, but subsequent transfers took some of the females out of touch of their initial group's range. Factors that determined whether or not a female stayed with her new unit will be considered later in this paper. Females transferred about equally often to lone males ($n = 11$ transfers) as to groups ($n = 9$ transfers). A number of these transfers were returns to previous units, two of them (possibly 4) to the presumed natal group. If returns are omitted, more females (6 compared with 4) transferred more frequently (9 transfers compared with 4) to more lone males ($n = 4$, possibly 5) than to groups ($n = 2$).

In only three of more than 20 observed potential transfer situations was a male observed actively to prevent a female from approaching the new male, in spite of its being presumably disadvantageous for a male to lose a female that is not his daughter. It seems that males inhibit female emigration more by prevention of proximity of other males than by herding females: of 12 interactions between units during which females transferred, 10 involved intense displays, and sometimes fights, between the males.

It is presumably advantageous to a male, especially a lone male, to gain an unrelated female. Thus, kidnap of females might be expected (Fossey, p. 334 in ref. 13). Out of eight observed visits or transfers, however, only one was possibly caused by coercion by the new male; the others were clearly of the females' own volition. (The discrepancy between the number of interactions (12) and the number of observed visits or transfers (8) is because much of the course of an interaction can be judged from the spoor alone.)

Table 1 Data on males aged 11 yr or more at the end of the study that (a) emigrated from their probable natal group* or (b) remained in it

*This group is almost certainly the natal group of the four infants. Ad, Sexually mature female (> 8 yr); sAd, subadult (6–8 yr); J, juvenile (3–6 yr); I, infant (0–3 yr). Ages are to the nearest 0.5 yr.

What factors influence a female's choice of male, and her decision to stay or transfer again? By analogy with ornithological studies[14], and with some data to support the suggestion, the initial decision might depend on the quality of the male's range. Subsequent decisions to stay or transfer might rest on the female's success at raising her offspring in the unit: two mothers who successfully raised their offspring in a new unit stayed; three who did not, left. The infants of at least two of the latter were killed deliberately during interunit interactions.

Finally, why are gorillas and chimpanzees, perhaps the only primates in which females more frequently transfer between units than do males? Four reasons are suggested. The first two are presented in terms of consequences of remaining in the natal group.

● Macaques are the best documented taxon in which males, but rarely females, transfer between groups[2,3]. Also well documented in this taxon is the phenomenon of offsprings' assumption of agonistic ranks close to that of their mothers', and of females keeping their rank from immaturity into adulthood[15,16]. Even if immature chimpanzee and gorilla females assumed ranks close to their mothers' (and gorilla females probably do not), there would be little advantage in doing so because of lack of competition in which dominance would be an advantage. Thus, to a gorilla or chimpanzee female, there are less advantages to remaining in her natal group than there are to at least a macaque female.

● Conversely, for chimpanzee males, there are advantages to remaining within their natal community because of communal defence of range and acquisition of females[6,17,18].

The final two reasons for female, rather than male, transfer in gorillas and chimpanzees are presented as proximate causes of the observed pattern of, first, emigrations, and second, transfers.

● Although the evidence is diffuse, it seems that young adult males and females tend not to copulate with familiar individuals[19]. Given the current state of transfers, females of many, perhaps most, group-living primate species can copulate with unfamiliar mates in their natal group; chimpanzee males can do the same with females; neither gorilla females, nor males (because the dominant male inhibits young males from mating) can do so; and we find that both young male and female gorillas leave their natal group.

● Resident gorilla and chimpanzee males seem more capable than do resident males of other species, of preventing non-group males from entering the group and mating; gorillas, because of small group size and rarity of oestrus; chimpanzees, because of communal attacks on strange males[17,18]. Thus gorilla males that leave their natal group (no chimpanzee males have been known to do so[5,6]) travel alone until females transfer to them, whereas in other species, the males themselves tend to transfer.

Female African wild dogs emigrate

AMONG mammals, the common mechanism of individual transfer between social groups is male emigration. While studying the African wild dog (*Lycaon pictus* Temminck) over a period of 2 yr, we have recorded four positive cases of female group emigration, three possible cases of single female emigration, and only one possible case of male group emigration. From this we conclude that female emigration is the primary mode of interpack transference in African wild dogs. The only other mammal for which this has been reported is the chimpanzee[1].

The African wild dog is a medium-sized carnivore living and hunting cooperatively in packs[2]. Average pack size during our study was 7.2 adults (computed at 3-month intervals for seven packs, an adult being 1 yr and older). Group social organisation in this species usually consists of one breeding pair per pack and a cooperative system of pup rearing by all pack members[3–7]. According to zoo records[7,8] and observations of very small pups at dens[7,9], the sex ratio is unequal at birth, with 55–59% males. Of 78 dogs 2 yr and older (and therefore sexually mature) that we studied, 69% were, however, males.

Fieldwork began in January 1974, and is continuing. Individual wild dogs are recognised by their distinct coat colour pattern (Fig. 1). For field identifications, a photographic recognition file is carried. Life histories and family relationships are recorded for all known dogs. These data are augmented by Hugo van Lawick's photographic recognition file for 1968–72. Our study area is 4,200 km² of grasslands and 1,000 km² of surrounding woodlands in northern Tanzania's Serengeti National Park and Ngorongoro Conservation Area. This includes the entire known ranges of four wild dog packs and part of the ranges of two additional

packs. Pack ranges cover a minimum of 1,500 km², and overlap about 10–50% with the range of each of the three or four neighbouring packs. Surrounding our study area there are at least seven more packs. We believe the wild dog population may be depressed by disease. Furthermore, shooting within the park as recently as November 1973 has entirely exterminated some packs.

Previous studies tended to concentrate on one pack of wild dogs, with only infrequent sightings of other packs. Changes in pack composition between sightings were therefore usually impossible to interpret. There are, however, two verified instances and one probable case, of female group emigration from the years 1968–71 (J. R. Malcolm and H. van Lawick, personal communication) in the same area as our study area.

Instances of emigration among our six study packs are shown in Fig. 2. In our study, emigration was verified when the following criteria were met: (1) the original pack was seen alive and intact after the disappearance of some of its members; (2) the missing dogs were seen alive after they had left; and (3) the missing dogs joined a new pack and did not return to their original pack. There were four verified cases of group emigration of females, involving 14 individuals. Four of these females emigrated twice.

Individual females disappeared from their packs in three further cases and were never seen again. Two of these females were sisters, who disappeared individually. Because they might have been expected to emigrate together, but did not, there is some doubt about whether they really emigrated. We believe that both probably did emigrate, however, because all pack members seemed to be healthy just before each sister's disappearance, one of their sisters had established herself as reproductively dominant, and both were of an age beyond which no females remain in packs as non-breeders. The one remaining sister of the dominant female who stayed in the pack was also able to breed. She was, however, clearly subordinant, and was allowed only limited access to her pups. Her mate was probably one of the subordinant males. In the third case, a lone daughter of the pack disappeared. She had no sisters which could have accompanied her, and she was the same age as other young females whose emigrations were verified. Each of these three females probably emigrated and died. Mortality of emigrating lone adult females may account significantly for the preponderance of adult males in the population.

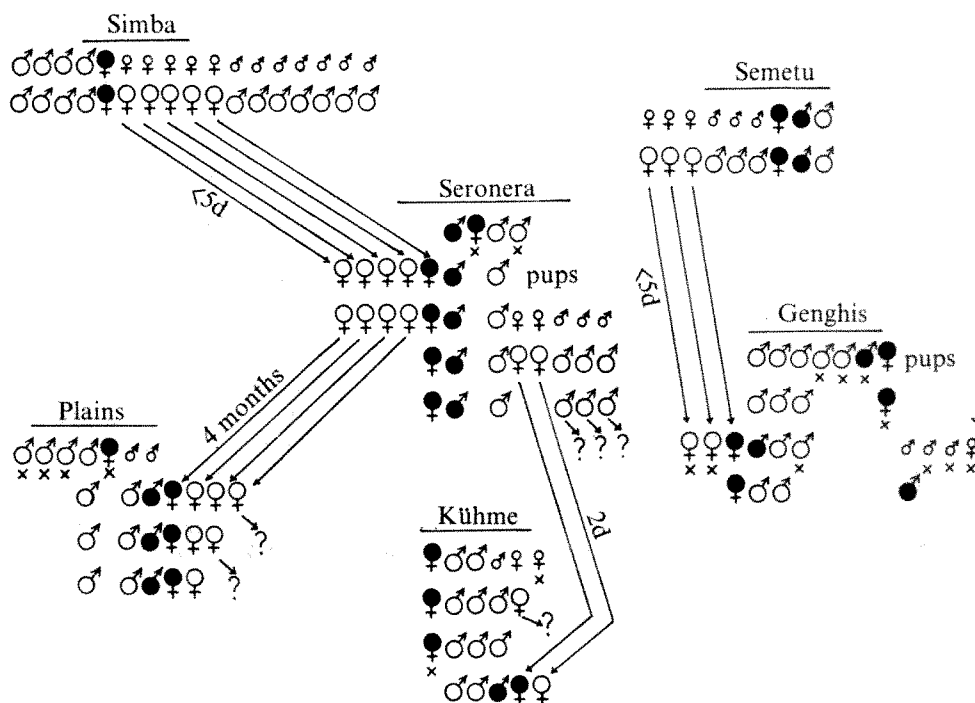
During our study, there was one unexplained dis-

appearance of three male siblings, just at the age of sexual maturity. They probably emigrated from their parent pack, but were not seen again.

In February 1976 we witnessed the emigration of two daughters from the Seronera pack to the three males of the Kühme pack. We followed them continuously for 6 d, which included their departure from the parent pack, their journey in search of the Kühme males, and their subsequent joining. Their emigration seemed to be precipitated by the proximity of the Kühme males who were without a female. The emigrating females tracked the scent trail of these males, and one of them repeatedly made contact calls. At the initial meeting of the two groups, there was a high level of aggressive pawing, shoving, and riding-up between the sexes, initiated by the females (Fig. 1). This behaviour continued for the subsequent 2 d of observation. Within 2 min of meeting, however, it became obvious which male and female would form the new breeding pair. One male excluded the other two males with threats, and one female excluded her sister with threats and attacks. Within 90 min this pair was urine-marking together, in the manner of a breeding pair[5]. Behavioural details of the emigration, and a general discussion of the dynamics of African wild dog packs, and the phenomenon of pack splits, will be published elsewhere[5].

The following main features of female emigration have emerged in 2 yr of study : (1) Female emigration occurred when a pack already had one breeding female. (2) Emigrating females never joined a pack that already contained a female. (3) Factors which drove or enticed females from their packs are obscure. The suddenness and rapidity of three transfers suggested an outside stimulus precipitating emigration, probably olfactory or visual evidence of a group of males nearby. There was no evidence that oestrus was the initiating factor, although all females were of the age of sexual maturity, and in one case oestrus and conception occurred soon after the females joined new males. (4) Females did not emigrate further than the adjacent or overlapping ranges of neighbouring packs. This was true in all cases, including the group of four females who roamed 4 months before joining new males. (5) Females usually emigrated in groups, if this was possible.

In the existing ecological conditions and low density of African wild dogs, female emigration has been the regular and predictable pattern of interpack transference. Male emigration has been of lesser importance, with no such transfers verified. In packs with offspring of known or
Fig. 1 Side view of three African wild dogs showing distinctive coat patterns used in individual identification. This photograph shows the two sisters (right), who emigrated from the Seronera Pack. During the third morning of their emigration, they met the males of the Kühme pack, who lacked females. A great deal of aggressive pawing, shoving, and riding-up was initiated by the females.

Fig. 2 Diagram of female transference among six study packs of African wild dogs. Three of the four transfers occurred within several days; the fourth took four months. Four females of the Simba pack underwent a secondary emigration after a sister became established as a breeding female in the Seronera Pack. Vertical columns represent the same individual through time. ♂, Adult male; ♀, adult female, ♂♀, dominant breeding pair, ♂ ♀, yearling littermates, ×, dead, ?, disappeared.


reliably estimated age, all daughters left when they were 18–24 months old. Their male siblings usually stayed in the parent pack. A process of secondary emigration existed, whereby sisters of a new breeding female left her after she attained this status. In combination with probable mechanisms which delay some females' breeding, emigration accounts for the usual occurrence of only one breeding female per pack. Differential mortality of females who emigrate singly or in small groups may account for the sex ratio favouring males more in adults than in immature dogs.

We thank the Trustees and Director of Tanzania National Parks, the Director of the Serengeti Research Institute, the Chief Park Warden of the Serengeti National Park, and the Conservator of Ngorongoro Conservation Area for permission to do this research. Baron Hugo van Lawick and James R. Malcolm shared information from their earlier fieldwork. Many others, especially Jerry Rilling, helped by providing data and photographs of their sightings of the dogs. Financial support was provided by the East African Wildlife Society, Max Planck Institut für Verhaltensphysiologie, the African Wildlife Leadership Foundation, the Shikar-Safari Club, Sigma Xi: The Scientific Research Society of North America, The Explorers Club, The Zoological Society of Philadelphia, the Fauna Preservation Society, Baron Hugo van Lawick, and The Fund for Animals Inc. The manuscript was critically read by J. D. Bygott, R. D. Estes, L. J. Folse, J. J. R. Grimsdell, J. P. Hanby, J. D. and S. H. Ligon, J. R. Malcolm, S. J. McNaughton, J. Rood, H. van Lawick, and W. Wickler.

Allometry of neonatal size in eutherian mammals

I HAVE demonstrated that neonatal weight in 15 species of anthropoid primates scales at a power of maternal weight of 0.70 (ref. 1). Gould[2] noted the closeness of this value to the standard metabolic exponent of 0.75, and asked if this similarity was more than coincidental. In an attempt to answer Gould's query, I have investigated the scaling of neonatal size in eutherian mammals and primates in particular.

Incorporated in this study are data on weights of neonates (foetus at term ± 5 d) and adult, non-pregnant females of 36 eutherian species ('mouse to elephant' curve)[3] and 29 primate species[4], in addition to previously unpublished data on 287 neonates and 316 females of seven species of *Macaca* (*M. fascicularis, M. radiata, M. nemestrina, M. niger, M. mulatta, M. arctoides* and *M. fuscata*).

Among eutherian mammals and subordinate eutherian taxa, neonatal and maternal weight are allometrically related through the equation

$$y = bx^a$$

where y is neonatal weight (weight of the whole litter if there is more than one offspring), b the initial size constant (y intercept), x the maternal weight, and a the exponent of allometry (slope)[3,4]. Table 1 and Fig. 1 show that there is a concomitant change of a and taxonomic level. This situation parallels the finding for the brain size–body size relationship[2]. On the other hand, for the scaling of the other principal organs (for example, heart, lungs and liver), the relationship between a and taxonomic level is far less regular[5–8] (Table 1 and Fig. 1).

An assessment of the various values of a with taxonomic level requires a causal explanation. In the scaling of brain size, the combined influence of differences in the evolutionary level of brain development and differences in mean body size of groups at the same taxonomic level accounts for differing values of a (ref. 2). Similarly, in the scaling of neonatal size, differences in the structure and physiology of foetal membranes and placenta in combination with differences in mean body size must be considered. Thus, a meaningful interpretation of a
Fig. 1 Neonatal–maternal weight relationships in Eutheria, Primates, Strepsirhini, Haplorhini and *Macaca* (based on values from Table 1).

in the scaling of neonatal size requires that either corrections are made for structural and physiological dissimilarities during foetal development, or comparisons are limited to taxa with members that are structurally and physiologically similar.

Among the Eutheria basic similarities in foetal membrane development only exist during early blastocyst formation[9], after which there is considerable variation in the development of foetal membranes and placenta among the higher taxonomic categories (orders and suborders)[9]. Because it is virtually impossible to quantify the influence of structural and physiological differences in foetal development on neonatal size for a taxon as diverse as Eutheria, a meaningful interpretation of a is difficult. In any case, a (0.83) for Eutheria is clearly above the standard metabolic exponent.

Primates are also variable in the foetal development of many features. For example, there is a strong dichotomy in the structure of the chorio-allantoic placenta and associated foetal membranes. The members of the suborder Strepsirhini have a non-invasive, diffuse, epitheliochorial placenta, a large allantois and a transitory chorio-vitelline placenta, whereas an invasive, discoidal, haemochorial placenta and rudimentary allantois characterise members of the suborder Haplorhini[9]. Although the standard metabolic exponent (0.75) is within a 95% confidence interval of a (0.78 ± 0.05) for Primates, this similarity may be merely coincidental. Actually, the value of a in Primates is due to the combined result of lower but similar values of a in the two suborders, the separation of the two suborders by an allometric shift (differing values b due to differences in foetal membrane and placental structures), and a difference in mean body size between the two suborders.

In contrast to the infraclass Eutheria and the order Primates, structural and functional similarity in foetal membranes and placenta exists within each of the suborders Strepsirhini and Haplorhini. It is interesting that, whereas the standard metabolic exponent (0.75) lies outside the 95% confidence interval of a for both Strepsirhini (0.63 ± 0.05) and Haplorhini (0.69 ± 0.04), another 'standard' exponent (0.67) is within these confidence limits. The value of 0.67 is known as the standard exponent for the interspecific ordinal scaling of brain size. It implies a determination of brain weight by body surfaces rather than by volume, a finding that has not yet been satisfactorily explained[2]. Similarly, it is difficult to explain the geometric similarity between neonatal weight and maternal surface. One explanation may be that, assuming (as for other organs[5]) virtual isometry of placental weight and maternal weight, placental surface rather than volume determines neonatal weight.

Among macaque species, a (0.49 ± 0.03) is clearly below 0.75 and 0.67. As with other aspects of scaling of neonatal size, a parallel situation exists in the scaling of brain size. Studies of brain–body size relationships in primates[10-13] have shown that brain weights in adults of a single species (or a cluster of related species so similar that they appear as different size expressions of the same body plan) scale at a much lower power of the body weight (generally between 0.2 and 0.4) than more distantly related species. As with intrageneric curves of brain size[2], the present findings on macaque species suggest that the low value of a in an intrageneric curve of neonatal size is probably a consequence of the intraspecific pattern which in turn represents the correlated variability on which selection acts.

In summary, the findings on neonatal–maternal weight relationships in eutherian mammals indicate that neonatal size is not scaled metabolically. In taxa that are structurally and functionally equivalent in foetal membranes and placenta, neonatal weight scales at a power of maternal weight close to 0.67. This suggests that maternal (placental) surfaces rather than volume determine neonatal size.

I thank W. P. McNulty, Oregon Regional Primate Research Centre, for weight data for macaque species and S. J. Gould, W. P. Luckett, G. T. Sacher, K. A. Bennett, J. T. Kelly, S. G. Larson and J. A. Vilensky for constructive criticism, and J. Noda for constructing the figure. Support was provided by a grant from the Graduate School, University of Wisconsin, Madison.

Phenotypic variability of inbred and outbred mice

THE relative phenotypic variability of inbred and commercially available outbred stock mice has never been satisfactorily investigated, even though it has important implications in the design of animal experiments. Early workers[1] suggested that "the published facts suggest that inbred strains are usually more variable than inter-strain hybrids, with random bred colonies occupying an intermediate position." Later it was concluded that with respect to phenotypic variability, "no

general law can be asserted on the comparison of inbred strains with randombred stocks"[2]. A subsequent debate on the suitability of inbred, outbred and F_1 hybrid mice for biological assay[3-6] failed to clarify the situation, and many research workers were left with the impression that inbred animals are more variable than outbred ones. Much of the early work could be criticised on the grounds that sample sizes were small, and few populations were sampled. We have collected extensive data on the phenotypic variability of the shape of the mandible, as part of a routine genetic quality control programme[7,8], and have found that assuming equal sensitivity to an experimental treatment 50% more outbred than inbred mice would be required to detect a 1-unit change in mandible shape.

Samples of mandibles from inbred (I), outbred (O), F_1 (F_1) and F_2 (F_2) hybrid mouse colonies were obtained from a number of locations and colonies, as summarised in Table 1.

The outbred stocks were named as: TO, BKW, CFLP, LACA, LACG, ICI, MF1, CD-1, CFW, Porton and CF_1. They were all commercially available "white mice" (except for the LACG) typical of those used for many research purposes. Inbred strains included the following, A, A2G, AKR, B10.BR, B10.A, B10.LP-*a*, BALB/c, C57BL, CBA/Ca, CBA/H-T6, CFNIH, C3H/He-*mg*, C3H/He, CE, C57BL/10, C57BR/cd, DBA/1, DBA/2, F/St, ICFW, NZW and 129/RrJ. The F_1 hybrid mice were (C3H × DBA/2)F_1 and (BALB/c × C57L)F_1. The F_2 hybrids were (NZB × NZW)F_2 and (BALB/c × C57L)F_2.

Each sample consisted of 8–28 (average 12) male mice over 6 weeks old, and usually weighing 25–30 g, and at least two separate samples were obtained from each colony.

Mandibles were prepared and measured as previously described[9] using 11 measurements per mandible, and the shape of each mandible was described by two discriminant functions

$$d_i = \sum_j \beta_{ij} X_j \qquad \begin{array}{l} i = 1, 2; \\ j = 1, 2 \ldots 11 \end{array}$$

where the β_{ij} are a set of constants given elsewhere (ref. 8, Table 3) calculated from a previous set of data (not included in this study) and the X_j are the individual measurements expressed as a percentage of the sum of the measurements, in order to

correct for variation in size of individuals. The traits d_1 and d_2 may be regarded as numerical indices of mandible shape corrected for size. The data analysed in this study are the within-sample standard deviation of the two discriminant functions d_1 and d_2, designated S_1 and S_2 in the 194 samples from the four different classes of stock. Although d_1 and d_2 discriminate well between strains, they do not discriminate between I, O, F_1 and F_2 classes, and there is no evidence for any association between mean and variance. Thus, the use of these two functions should not introduce any bias when comparing the four classes of stock. Also, d_1 and d_2 are uncorrelated.

Assuming that the two characters d_1 and d_2 have a polygenic mode of inheritance, the variation within the F_1 crosses should give a direct estimate of the environmental variance V_E. The total genetic variance (including additive and non-additive components) within the F_2 and O classes of stock may then be estimated by subtraction.

The distribution of the within-sample standard deviations is shown in Fig. 1 for trait S_1. Within the inbred class of stock there was no evidence that some strains were more variable than others. Similarly, there was no evidence that some of the outbred colonies were more variable than others, though Fig. 1 shows that the variation between samples was greater than with the inbreds, and as some are likely to be more inbred than others, differences could have been expected.

Pooling the data within each class of stock, the following relationships for phenotypic variability were established

$$\text{Trait } S_1: F_2 > {}^*O > {}^{**}I > F_1$$
$$\text{Trait } S_2: F_2 > {}^*O > {}^{**}I > F_1$$

*Significant $(0.01 < P < 0.05)$
**Significant $(P > 0.01)$

The mean phenotypic standard deviation in each class of stock, together with standard errors, is summarised in Table 2. Inbreds were slightly but not significantly more variable than F_1 hybrids, but were substantially less variable than the outbreds, which in turn were less variable than the F_2 hybrids.

Table 1 Animals used in the study

Classification	F_2	O	I	F_1	Total
Locations	1	7	5	5	—
Colonies	2	14	28	2	—
Named stocks	2	11	22	2	37
Samples	10	63	107	14	194
Mice	114	873	1,101	256	2,344

Fig. 1 Distribution of the within-sample phenotypic standard deviation of an index of mandible shape in F_2 hybrid, outbred (O), inbred (I) and F_1 hybrid mice. Arrows indicate the mean, *n* is the number of samples. Sample size averaged 12 mice.

Table 2 Mean phenotypic standard deviation (and its standard error) of two indices of mandible shape ($\bar{S}_1$ and $\bar{S}_2$)

Class of stock	No. of samples	$\bar{S}_1$	s.e.	$\bar{S}_2$	s.e.
F_2	10	1.73	0.161	1.52	0.101
O	63	1.49	0.055	1.39	0.050
I	107	1.14	0.022	1.06	0.030
F_1	14	1.01	0.043	0.97	0.056

Estimates of the environmental variance, and the genetic variance within the F_2 and O stocks is given in Table 3. Heritabilities (in the broad sense) of d_1 and d_2 were estimated as 0.66 ± 0.175 and 0.59 ± 0.216, respectively. As single-cross F_2 stock has a coefficient of inbreeding of 0.5 (ref. 10), the relatively low genetic variance of the O stock compared with the F_2 stock implies a substantial degree of inbreeding, probably equivalent on average, to four or more generations of brother × sister mating.

This study shows unequivocally that for these two highly heritable polygenic characters outbred stocks are substantially more variable than inbreds. The implications in terms of number of animals required in an experiment may easily be

Table 3 Genetic and environmental variances

Variance	Estimated from	Trait S_1	s.e.	Trait S_2	s.e.
V_E	V_{F_1}	1.02	0.061	0.94	0.076
$V_{G_{F_2}}$	$V_{F_2} - V_{F_1}$	1.97	0.398	1.37	0.230
$V_{G_0^{F_2}}$	$V_0 - V_{F_1}$	1.20	0.129	0.99	0.124

calculated on the assumption that none of the classes of stock is likely to be more sensitive to an experimental treatment than another. In these circumstances, an experiment set-up to detect a 1 unit change in mandible shape between treated and control groups (assuming type 1 and 2 errors are set at 5%, and 10% respectively) would require 13 F_1, 16 I, 25 O or 34 F_2 animals. Thus, in this case, more than 50% more outbred than inbred animals would be required, though the difference would not be so large in the case of characters with a lower heritability.

These findings give added support to the case for the more widespread use of inbred strains[11].

I thank Mr W. Peacock for technical assistance.

Fine structural changes in human astrocyte carrier lines for measles virus

Chronic infection with measles virus is causally related to the human syndrome of subacute sclerosing panencephalitis (SSPE)[1-5], and means of reproducing that condition in experimental animals are being sought[6-10]. Measles carrier states *in vitro* have been established in some human[11-13] and rodent[14,15] cell systems. We now report the establishment of measles carrier states in human astrocyte cultures of normal brain, and in a tumour astrocyte line, as well as the emergence of fine structural features which bear a close resemblance to findings in the brain of some patients with SSPE[16].

Two strains of measles virus were used—wild type (WT) derived from a pharyngeal swabbing of a patient with measles, and Edmonston (ED), a laboratory strain[17]. Infectivity (TCID$_{50}$/0.1 ml of cell-free supernatant), haemagglutination (HA) and neutralisation titrations followed published procedures[17-19], as did primary and secondary cell culture techniques[20]. The same batches of Eagle's MEM and of foetal calf serum were used throughout.

In initial work to establish measles carriers we used the 1N1 tumour astrocyte line[21]; equivalent 1N1 cells had been used successfully to initiate the V-1N1 line of visna virus-producing human astrocytes[22]. Subsequent work with astrocytes derived from two normal foetal brains (HFA1, HFA2) and with WT virus gave an essentially similar pattern of virus–cell interaction. The following description of the establishment of the ED-human tumour astrocyte line (ED-1N1) will therefore serve, save for minor variations of time scale, for the ED carriers derived from normal astro-cytes (ED-HFA1; ED-HFA2) and the WT astrocyte carriers (WT-1N1; WT-HFA1; WT-HFA2).

1N1 cells at passage 125 were used. At this passage level, the cells contain glycogen[21], synthesise high levels of adenyl cyclase[23] and respond appropriately to catechol stimulation[24], as befits astrocytes. 1N1 cultures at a density of 1×10^4 cells per mm² were exposed at 37 °C to 0.01 TCID$_{50}$ ED virus per cell for 2 h, then rinsed and returned to growth medium. Binuclear cells were plentiful in 2 d, small syncytia in 3, huge syncytia in 5; cytolysis began on about day 5 and was almost total by day 9. Intranuclear and cytoplasmic inclusions were made visible by Giemsa staining. Infectivity titres at day 7 after infection were $10^{4.5}$ TCID$_{50}$ and HA was 14–28. These results are in accord with an acute cytolytic infection of classical type by measles virus[17,19].

In occasional cultures, scattered cells survived for 14 d; such survivors were likely to develop into carriers. The ED-1N1 line was derived from cells infected as above: a few discrete cells survived for 9 d after infection; these were elongated and had prominent paranuclear vacuoles. At 14 d after infection five small cell groups were present; 25 d after infection mitoses were frequent; the most common cell was plump and fusiform. Small syncytia appeared 31 d after infection among the other cells, grew slowly to maximum size (always much smaller than in cytolytic states) in 8 d and eventually rolled off, while other syncytia developed. The predominant cell was mononuclear. At 60 d after infection the cells were trypsinised for the first time, and designated

Fig. 1 *a*, Intranuclear inclusion, as seen in cytolytic cultures of 1N1 cells 5 d after infection with ED measles virus. Higher magnifications (*b*) show them to consist of arrays of 16-nm smooth nucleocapsid tubules. From fourth transfer onwards, such tubules were not observed in the carrier lines. The bar represents 500 nm.
Fig. 2 *a* and *b*, Development and structural detail of complete measles virions at the cell surface, as found in both cytolytic and carrier cultures. *c*, Structurally defective particles observed (beside complete virions) from fifteenth transfer stage in the carrier lines. Note the lack of external projections and disorderly packaging of the nucleocapsids. The bar represents 500 nm.

ED-1N1[?]. Intranuclear and cytoplasmic inclusions were present in both fusiform cells and syncytia. Infectivity titres at this stage were 10^3 TCID$_{50}$. Between transfers 5 and 15 they were consistently 10^5 TCID$_{50}$, while HA titres were 28–56 and anti-measles neutralisation stood at 1/4. In later transfers, interference was evident, that is, no syncytia were expressed at 10^0, 10^{-1} and $10^{-1.5}$, but they were seen at high dilutions of virus. Morphologically atypical virus was detected subsequently in electron micrographs of such cultures. So far the ED-1N1 line has had 21 trypsinisations; this covers 32 weeks from initial trypsinisation. The cells continue to grow well, to produce inclusions and scattered syncytia, and virus titres now stand at $10^{3.5}$ TCID$_{50}$. The HA titres of the WT lines (WT-1N1; WT-HFA1; WT-HFA2) are 128–256; those of the ED lines (ED-1N1; ED-HEA1; ED-HEA2) are 14–28. The WT lines are at transfer 12.

For electron microscopy[21,25] representative cultures of the 1N1 cells 5 d after infection with ED strain and from transfers 3 to 21 of the noncytolytic ED-1N1 carrier line were compared with equivalent transfers of uninfected HFA1, HFA2 and 1N1 cells, and with WT-1N1[6,12], WT-HFA1[6], WT-HFA2[6] and ED-HFA1[6] carrier lines.

The ultrastructure of the cytolytic cultures showed all the usual intranuclear and cytoplasmic features (see for example, refs 26 and 27) (Fig. 1*a* and *b*). Extracellular virions featured a surface layer of 8-nm projections, characteristically thickened envelope membrane, and nucleocapsid tubules disposed peripherally in spiral form (Fig. 2*a* and *b*). The infected nuclei also had many rounded condensations of microfilamentous material resembling the "nuclear bodies" of normal cells[28].

Between transfers 3 and 21 of the ED-1N1 carrier line there were three morphological changes: (1) the dis-

appearance of measles intranuclear nucleocapsids, (2) the appearance in the nuclei of complex structures seemingly derived from nuclear bodies and (3) the emergence of a proportion of morphologically defective virus particles at the cell surfaces. Intranuclear aggregates of measles nucleocapsid[26,27] were not found in any of the carrier cultures. In rare cells at transfer three scattered tubular profiles were found whose size matched that of smooth nucleocapsid. From the fourth transfer onwards, even these occasional structures were absent. At this stage, however, unusually large nuclear bodies (up to 800 nm diameter) became frequent, some with centrally placed clusters of vesicles (Fig. 3*b*). By transfer 7, enlarged, structurally abnormal nuclear bodies, from 500 nm to 3.5 μm in diameter and with a well developed membranous component, were a feature of almost all the cells. Four types could be recognised, perhaps representing different developmental stages: (1) simple microfilamentous, (2) vesicular, (3) complex laminar and (4) cisternal (Fig. 3*a–d*). A single nucleus often held different types. Such bodies were invariably demarcated from surrounding nuclear structures by a peripheral zone of microfilamentous matrix, like that of nuclear bodies in control cells[28]. The new structures were easily distinguished from nucleoli or infoldings from the nuclear envelope. Most striking were the large laminar and cisternal types, in which paired membranes formed closely coiled profiles, with various degrees of focal distension or ballooning. A layer of fine (9–10 nm) regularly spaced filaments often was intercalated between the paired membranes (Fig. 3*c*). Such modified nuclear bodies, and an absence of measles intranuclear nucleocapsid tubules, also characterised the other carrier lines. Extensive surveys of uninfected cultures showed normal small nuclear bodies; no suggestion of the more complex structures was ever seen.

All carrier lines had numerous, large cytoplasmic inclusions akin to those found in cytolytic cultures. Virus particle morphogenesis was evident in all carriers; but in later transfer stages, especially the 15th and 21st transfers

Fig. 3 Four types of nuclear bodies, present within nuclei of ED-1N1 carrier cultures at fourth and seventh transfer stages: *a*, simple microfilamentous; *b*, vesicular; *c*, complex laminar; *d*, cisternal. The more elaborate forms were a prominent feature from the seventh transfer stage onwards. The bar represents 500 nm.
of the ED-1N1 line, other types of membrane-bound particles were also found (Fig. 2c); their envelopes resembled unmodified host plasma membrane, lacking external projections or thickening of the unit membrane. The contained nucleocapsid tubules lacked the characteristic peripheral and spiral disposition of complete measles virions (Fig. 2a and b). These were considered to be morphologically defective measles particles: their presence would seem to complement the observation of viral interference noted in infectivity titrations.

We conclude that the measles carrier lines exhibited a common pattern of fine structural changes, whether derived from normal or tumour astrocytes and whether infected with ED or WT virus. It would be interesting to know whether measles vaccine preparations can induce a similar *in vitro* response in suitable host cells. A prominent feature of the carrier lines, not reported previously even in long term measles-infected organ cultures[14], was the emergence of complex intranuclear formations interpreted as modified nuclear bodies. Martinez *et al.*[16], in a review based on eight autopsied cases of SSPE, defined a category of nuclear inclusions believed to be of diagnostic significance and representing altered nuclear bodies, distinct from paramyxovirus-like nucleocapsid tubules also reported in this disease[1-5,26,27]. Enlarged nuclear bodies of the same kind were in evidence from the third transfer onwards in our astrocyte carrier lines, together with even more elaborate forms with a well developed membranous component. Simple hypertrophy of nuclear bodies is well known in measles, and some other virus infections[28], but their relationship, if any, to synthesis of specific viral components is still largely speculative. SSPE is associated with a defective form of measles virus[4]. Although the carrier lines continued to produce infective virus throughout, evidence of defective particle production was also obtained.

Functional and structural features of the measles carrier state in human astrocytes seem therefore to present interesting parallels with the disease SSPE.

Environmental carcinogens and large bowel cancer

The geographical variation in the incidence of large bowel cancer together with the increased incidence found in migrants from low risk to high risk areas support the view that environmental factors are involved in the aetiology of this disease[1]. These environmental factors are thought to be largely dietary although other influences have not been excluded. Aries *et al.*[2] suggested that the disease is caused by carcinogens produced by gut bacteria from bile acids. Diet would influence both the bile acid levels in the bowel and also the nature of the gut flora. Faecal bile acids are more concentrated in faeces from people living in high incidence areas than in faeces from populations at low risk[3]. Similarly, faecal bile acids are usually more concentrated in samples from patients with large bowel cancer than in those from control patients[4]. Bile acids were postulated to be the substrates from which the gut flora produced carcinogens[2] and indeed this suggestion has been supported by the demonstration that the faecal concentration of bacterially degraded bile salts is more highly correlated with the incidence of large bowel cancer than is the total bile acid level[3]. However, it has been suggested that the primary role of bile acids is as co-carcinogens and this suggestion is supported by the results of animal experimentation demonstrating the promoting effect of bile acids on the action of known carcinogens[5]. If it is accepted that bile acids act as co-carcinogens it becomes necessary to explain how the carcinogen reaches the large bowel without producing cancers in other parts of the gastrointestinal tract. Here we describe preliminary investigations of a mechanism by which an environmental carcinogen could be transported to the large intestine.

The conjugates and metabolites of benzo[a]pyrene were prepared biologically. This compound has been shown to undergo oxidation and conjugation in the rat and is excreted mainly in the bile as glucuronic acid and sulphate conjugates of phenols, as conjugates of dihydrodiols and possibly as mercapturic acid conjugates[6,7]. Two bile duct cannulated female Wistar albino rats were given 7,10,14-^{14}C-benzo[a]pyrene (Radiochemical Centre, Amersham); 1 mg; 14 μCi per rat. The bile was collected for 4 h and found to contain 6.7 and 12.5% of the administered ^{14}C. Analysis by thin layer chromatography[8] showed a single peak of radioactivity at the origin, corresponding to conjugated metabolites. Aliquots of the pooled bile containing the ^{14}C metabolites of benzo[a]pyrene were incubated with samples of human and rat faeces homogenised in nutrient broth. Further aliquots of the bile were incubated with pure cultures of bacteria representing the major types found in the intestine. After incubation for 72–96 h under strictly anaerobic conditions the reaction mixtures were analysed by thin layer chromatography.

Almost all the bacteria tested were able to hydrolyse the conjugates to release the oxidative metabolites of benzo[a]pyrene (Table 1) and the major conjugated metabolites of benzo[a]pyrene seem to be phenols and quinones. It is, however, possible that further metabolism of the unconjugated metabolites may have occurred, and these phenols may have been produced from or converted to dihydrodoils and, to some extent, to benzo[a]pyrene. Of particular interest are the findings that the organism releasing the greatest amount of the parent hydrocarbon in this test system, *Clostridium paraputrificum*, is present in larger numbers in the faeces of "western" subjects[9] than in faeces from low risk areas, and the *Bacteroides* spp. show this activity as well as deconjugation of taurocholate and dehydroxylation of bile acids.

Table 1 The bacterial hydrolysis of the conjugates of benzo[a]pyrene excreted in the bile of rats

| | | Proportion of benzo[a]pyrene and its metabolites | | |
	Conjugates hydrolysed (%)	Dihydrodiols	Phenols and quinones	Benzo[a]pyrene
Rat faeces	28.0	15.9	11.3	0.7
Human faeces	28.4	10.2	17.1	0.9

The results are expressed as the percentage of the total radioactivity in the incubate.

Rat bile (100 μl) containing the conjugated metabolites of benzo[a]pyrene was incubated at 37 °C under anaerobic conditions for 72–96 h. Incubation in the absence of microorganisms showed a limited hydrolysis and conversion to benzo[a]pyrene, that is 10.0 and 0.5% respectively, which has been subtracted from the bacterial incubations to give the above results.

These preliminary experiments show that bacteria of the types found in the human intestine are able to hydrolyse the conjugated metabolites of benzo[a]pyrene excreted in the bile of the rat. A small, but significant, amount of benzo[a]pyrene was also released, probably as a result of the dehydroxylation of hydroxylated metabolites. These reactions are a reversal of the detoxication processes performed by the liver. An analogous mechanism is thought to explain the intestinal cancers produced in rats as a result of the administration of 3-methyl-4-aminobiphenyl and 3-methyl-2-aminonaphthalene, and the relevance of such studies with aromatic amines to large bowel cancer was reviewed by Weisburger[10].

Polycyclic aromatic hydrocarbons, such as benzo[a]pyrene, are widely distributed in nature and arise mainly from the combustion of organic matter, especially fossil fuels. Their concentration in the environment is thus increased by industrial activity. Engst and Fritz[11] showed concentrations of 0.8 μg kg^{-1} in sea sand, up to 0.8 mg kg^{-1} in rural soils but 65 mg kg^{-1} in the industrial urban environment. These compounds also occur in smoked foods. We suggest that polycyclic aromatic hydrocarbons such as benzo[a]pyrene ingested from the environment may act as the primary carcinogens in the development of large bowel cancer. The geographical variations in the incidence of this disease could then be partly explained in terms of the variations in the distribution of the carcinogens associated with industrial activity, since the incidence of colon and rectal cancer is highly correlated with gross national product[12].

The consumption of a western diet, rich in fat and protein, is undoubtedly also important. Diet probably influences the metabolism of polycyclic aromatic hydrocarbons directly, as a result of its influence on mucosal enzymes and indirectly by the effect on bile acid metabolism. Aryl hydrocarbon hydroxylase activity is present in the duodenal mucosa of rats fed fat-containing diets and may be induced by exposure to benzanthracene. The enzyme is present at very low levels in the mucosa of rats fed fat-free diets and is detected in the colon of rats fed fat-containing diets only after exposure to benzanthracene[13]. The levels of other enzymes, associated with benzo[a]pyrene metabolism in the gut wall, have not been extensively investigated.

There are two ways in which bile acids may be important in the metabolism of polycyclic aromatic carcinogens excreted in the bile. (1) The conjugated metabolites of benzo[a]pyrene in the bile are amphipathic compounds, as are the bile acids. An important function of bile acids is the formation of mixed micelles during fat digestion and it is possible that polar conjugates are incorporated into micelles thus aiding their transport through the small intestine. (2) Polycyclic aromatic hydrocarbons are lipid soluble and it has been suggested that this property would render them inactive in the aqueous environment of the gut[14]. Bile acids are,

however, powerful solubilising agents and would maintain the carcinogens in solution and aid their interaction with cell surfaces.

In conclusion, we would suggest that large bowel cancer results from the retoxification by the gut flora of the liver metabolites of polycyclic aromatic hydrocarbons. This process is influenced by the effect of diet on the intestinal cells and secretions, particularly bile acids and possibly by the effect of diet on the gut flora. The disease is more common in western countries because (1) industrial activity increases the amounts of polycyclic aromatic carcinogens in the environment and (2) the western diet favours the retoxification process.

T–T cell collaboration during *in vivo* responses to antigens coded by the peripheral and central region of the MHC

MIXED lymphocyte culture (MLC)[1] has been used extensively as an *in vitro* model to analyse the reactivity of T cells to antigens coded by the major histocompatibility complex (MHC). When murine T responder cells are exposed *in vitro* to allogeneic lymphoid cells (stimulator cells) they proliferate and cytotoxic T lymphocytes (CTL) are generated[2,3]. Antigens coded by the central I region of the MHC are chiefly responsible for triggering prolifer-

	(CBA×ATH)F$_1$ $\left(\dfrac{s\ \ s\ \ s\ \ d}{k\ \ k\ k\ \ k}\right)$	+ + + + +	29,000 ±2,600	92	34

The MLC system used to assay for proliferative responses (^{3}H-thymidine uptake technique) is that described by Peck *et al.*[21]. Splenic responder cells (0.25×10^6 cells per well) were incubated with 0.25×10^6 X-irradiated (2,000 rad) splenic stimulator cells in MLC medium[21] supplemented with 0.5% fresh mouse serum and 5×10^{-5} M 2-mercaptoethanol (ME) in flat bottom microtitre plates (Greiner, Nurtingen/Germany) over a period of 3.5 d. The cells were then pulsed with 1 μCi ^{3}H-thymidine per well for 7 h and processed as described[22]. Six replicate cultures per group were formed. The data given represent the mean ± s.d. The culture system used for the development of CTL has been described elsewhere[7,9]. Briefly, 3×10^6 responder cells were cultured together with 1.5×10^6 irradiated stimulator cells in Marbrook flasks containing MLC medium supplemented with 5% FCS and 5×10^{-5} M ME. After 5 d the cultured cells were titrated for cytotoxicity against LPS-induced blast lymphocytes[9] in a ^{51}Cr assay as described[7,9]. The lysis values given (mean of three determinations) were obtained at a ratio of attacker cells to target cells of 30 to 1: the data are given without s.d., since in the experiments listed the s.d. of percentage specific lysis was less than |4| %. Background lysis during the 3-h assay was less than 18%. The letters within the brackets denote the H-2 genotype of the respective cells.

ation[4,5], whereas the target antigen of the CTL generated is either a H-2K or H-2D region or a I–A subregion gene product[5-8]. This dichotomy in the antigenic requirement of a MLC seems to be reflected at the level of the responding T lymphocytes. Two distinct subsets of T cells (T_1/T_2), which have been defined by both functional[9,10] and physical[11] criteria and possibly on the basis of their Ly phenotype[12], seem to act synergistically during the *in vitro* generation of CTL[9-13]. Proliferating T_1 helper cells are thought to respond mainly to I-region gene products[2,5,12] whereas the precursors of CTL (T_2 cells) are believed to react specifically to transplantation antigens coded by the H-2K, H-2D, or I–A region[2,5,7]. The proliferating T_1 helper cell is believed to potentiate the development of CTL either by itself or through a secreted helper factor[2,11,13,14]. A serious limitation of this concept is, however, that so far the experimental evidence available is derived from work performed *in vitro*. We therefore aimed at verifying T–T collaboration during *in vivo* responses to antigens of the MHC.

The mouse strains we used were chiefly strains ATL, ATH and CBA/J. CBA/J and ATL mice are identical for the H-2I region, whereas ATL and ATH mice share the same H-2K and H-2D regions, but differ at the I region[15]. The results presented in Table 1 were obtained *in vitro* and demonstrate the effect of allogeneic, I-region-coded determinants on the generation of CTL specific for antigens coded by the H-2K and H-2D region. Thus ATL responder T cells proliferate strongly in response to I-region-incompatible ATH stimulator cells. In this combination no CTL reactive against antigens of the H-2K or H-2D region of the H-2^k haplotype are generated (the CTL generated are reactive against antigens of the I–A^k subregion[7]). On the other hand, ATL responder cells respond with a moderate cell proliferation to H-2K and H-2D region-incompatible CBA stimulator cells, and anti-H-2K^k and anti-H-2D^k region-specific CTL are generated. In the presence of "third party" ATH stimulator cells, however, the generation of H-2K^k and H-2D^k region-specific CTL is strongly enhanced. These results basically confirm the work of Bach and associates[5,13,16] and stress the collaborative effect of I-region-coded determinants on the *in vitro* generation of anti-H-2K and anti-H-2D region-specific CTL.

To find out whether during the induction of an *in vivo* allograft reaction a similar collaborative mechanism is operating, the following experimental protocol was applied:

a fixed number of distinct H-2 region-incompatible stimulator cells were injected into the hind footpad of ATL mice. After 3 d the draining lymph nodes were isolated, teased and single-cell suspensions were prepared. The cells were cultured (without adding stimulator cells) for 48–72 h more at 37 °C, a period required to allow full differentiation of the sensitised CTL precursor (A. St-P., in preparation). After this the lymph node cells were tested for the presence of CTL in a ^{51}Cr-cytotoxicity assay. Results of a typical experiment are given in Table 2 and indicate *in vivo* an even more pronounced amplification effect of I-region incompatibility on the generation of H-2K and H-2D specific CTL compared with the *in vitro* data (Table 1). Thus the capacity of H-2K and H-2D region-incompatible stimulator cells to provoke a specific CTL response was greatly increased

Table 2 Collaborative effect of *in vivo* responses to antigens coded by the peripheral and central region of the H-2 complex

Recipient	Irradiated stimulator cells (10^7)	H-2 incompatibility K,IA,IB,IC,D	% Specific lysis of targets CBA (k kkk k)	ATH (s sss d)
	ATL (s kkk d)	— — — — —	0	1
ATL (s kkk d)	ATH (s sss d)	— + + + —	4	19
	CBA (k kkk k)	+ — — — +	12	3
	ATH (s sss d) plus CBA (k kkk k)	— + + + — plus + — — — +	76	27
	(CBA×ATH)F$_1$ $\left(\dfrac{s\ \ s\ \ s\ \ d}{k\ \ k\ k\ \ k}\right)$	+ + + + +	69	24

ATL mice (recipients) were injected with either 10^7 ATL, or ATH, or CBA, or F$_1$ (CBA×ATH), or a mixture of both 10^7 CBA and 10^7 ATH mouse derived irradiated splenic lymphocytes into the left hind footpad. After 3 d the draining lymph nodes (LN) were dissected, single-cell suspensions were prepared and the cells were cultured for 3 more days *in vitro*. In general about 4×10^6–6×10^6 cells were obtained per LN. Thereafter, the cells were titrated for cytotoxicity in a ^{51}Cr assay[7] against LPS-induced target cells[7]. The percentage specific lysis values given were obtained at a ratio of attacker cells to target cells of 30 to 1. Collaborative effects of I region-incompatible stimulator cells were obtained with as few as 2×10^6 ATH stimulator cells injected together with 10^7 CBA stimulator cells (unpublished results). Background lysis of the target cells was less than 16%.

provided I region-incompatible stimulator cells were simultaneously injected into the hind footpad. In other words, the magnitude of the CTL response generated towards antigens coded by the peripheral K or D region of the H-2 complex was amplified by an I region-dependent stimulus presented separately on a "third party" cell.

From the experiments, we conclude that the collaborative effect of a T-cell response to I region-incompatible allogeneic stimulator cells on the generation of anti-H-2K and anti-H-2D-specific CTL seems to take place *in vivo* as effectively as *in vitro*. Since the target antigens of CTL are believed to be the transplantation antigens coded by the H-2K and H-2D region and I-A subregion of the H-2 complex[5,7], and since CTL are thought to be primarily responsible for allograft rejection *in vivo*[3], the *in vivo* immunogenicity of grafted allogeneic cells seems to be strongly dependent on whether or not they express the phenotypical products coded by the I region of the H-2 complex, besides H-2 transplantation antigens. Because lymphoid cells express antigens coded by both the peripheral and central region of the H-2 complex, our results are compatible with the concept that passenger leukocytes[17] may heighten the immunogenicity of transplanted allogeneic tissue grafts. They also offer an explanation of why anti-Ia antibodies eventually result in graft prolongation[18], and are compatible with the finding that allogeneic thyroid transplants are rapidly rejected, provided the recipient's T lymphocytes are sensitised against I region coded cell surface antigens[19,20].

Possible mechanism for the biological action of lithium

IN spite of considerable early controversy it is now generally recognised that lithium has a favourable therapeutic effect on affective disorders and for some years lithium salts have been used with some degree of success in medical practice[1,2]. Curiously, in spite of the extreme simplicity of lithium as a drug, there is little understanding of its mode of action. In this article we outline a possible explanation.

Lithium as a drug is given in the form of a simple salt and
Fig. 1 Uramildiacetic acid

the active agent is undoubtedly the lithium cation. The dose level, around 1 mM, in the body, is extremely high and the most likely action of lithium is that it challenges one of the common biological cations Na^+, K^+, Mg^{2+} and Ca^{2+}. This explanation meets, however, with an immediate difficulty in that it is very hard to find an example of an organic ligand which can bind lithium with a stability constant as high as 10^3 and yet does not bind Mg^{2+} and Ca^{2+} with much higher affinity (Table 1). In other words, Table 1 seems to show that there is no ligand which lithium could bind in the presence of these cations. In this note we wish to show that the use of Table 1 in this fashion is completely misleading as to the possible action of lithium within the context of biological media, which amounts to saying that chemical affinities measured by absolute values of stoichiometric stability constants do not give the true tendency for preferential binding of a certain metal ion if other potential complexing agents are also present and that the free metal ion content of the compartment under discussion must be known. A better approach is to use 'conditional' stability constants,which are constants valid for the medium in which the reaction is taking place. The discussion then has much in common with that used in analytical chemistry where less stable metal complexes are preferentially formed by a metal M_1 with a ligand L_2 by 'removal' of other metals M_2 by 'sequestering' or 'masking' agents L_1 which bind M_2 differentially more strongly, that is, under the conditions of the experiment $K_{M_2L_1} \gg K_{M_1L_1}$ such that $K'_{M_1L_2} > K'_{M_2L_2}$.

We start the analysis of the binding of the five cations Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+} to different ligands by using as a convenient measure of the uptake tendency of a certain ion by a certain ligand the product K'_{ML} [M], where K'_{ML} is the

'conditional' stability constant of the complex formed between that ion and ligand concerned and [M] is the concentration of metal ion in solution in the compartment[3].

In the case of prolonged lithium therapy, the concentrations of the common alkali- and alkaline-earth metals in the cytoplasm of cells will be close to those given in Table 2. In the cells there are not many good ligands of comparable concentration but, strikingly, adenosine triphosphate (ATP) is often present in a very comparable concentration range. In some vesicles, such as the adrenal chromaffin granule, the ATP concentrations may reach even higher values; typical results are Ca^{2+} — 14 mM, Mg^{2+} — 6 mM, K$^+$ = 20 mM ATP — 100 mM (ref. 4 and A. Daniels and R. J. P. W., unpublished). Leaving such special regions of the cell aside for the moment, we see that inside the cytoplasm of cells generally lithium will be selected preferentially to sodium and potassium if log K$'_{Li}$ is greater than log K$'_{Na}$ and log K$'_{K}$ by a factor of 2. Several ligands meet this requirement. Lithium will be selected preferentially to calcium by any ligand which has a conditional stability constant which is not more than 3 log units smaller for the lithium complex and even up to a difference of 5 log units there will be appreciable competition of lithium for calcium sites. This is easily achieved by many ligands which have log K$'_{Li}$ of about 3 (that is conditional constant at pH = 7). Thus the calcium ion in cells will not prevent lithium binding. Magnesium poses a greater problem for it is present in equal or greater concentration than lithium and we must now examine competition between ligands for magnesium and lithium.

Let us take the situation in the cytoplasm when Mg^{2+} (total) < ATP (total) and examine the effect of this background of relatively high ATP concentration upon the conditional stability constant of lithium and magnesium complexes with some chosen ligands (Table 1).

One of the most stable lithium complexes known is that of

uramildiacetic acid ligand (Fig. 1)—which has been studied in detail by one of us[6,7].

The values given in Table 2 were used to calculate 'conditional' stability constants for the magnesium and the lithium complexes of uramildiacetic in the presence of 10$^{-2.5}$ M free ATP. The results are presented graphically in Fig. 2 and it can be seen that for the conditions prevalent inside cells, as described above, although the magnesium complex remains the most stable of the two, lithium is likely to interfere and compete with magnesium to some 20–30% for its binding sites.

It is perhaps worthwhile to point out that the choice of uramildiacetic acid is not arbitrary, as there are obvious analogies between uramildiacetic acid and some compounds from which it actually derives, for example, barbituric acid and uric acid, curiously enough associated with lithium therapy from the very beginning. Hence Lipowitz and Garrod[8] refer to the combination of lithium with uric acid promoting the dissolution of urate deposits in cartilages and, more recently, Margulies[9] used lithium in combination with barbiturates obtaining favour-

Table 2 Concentration of common alkali earth metals and of ATP in cytoplasm of cells

able results in the treatment of manic states. Protective effects on urea toxicity in urine from manic–depressive patients injected to guinea pigs was also reported by Case[10].

Nevertheless, uramildiacetic acid as such does not occur in biological systems and the conclusion to be derived from the result expressed in Fig. 1 is that chelating sites of liganding atoms (O⁻, N, O⁻, O⁻) are likely to exhibit increased affinity for lithium and, in the presence of alkaline-earth metal sequestering agents, this metal may compete to a greater or lesser extent with Mg^{2+} and Ca^{2+} for the above mentioned sites.

As a matter of fact it is not necessary that the ligands have a particularly high affinity for lithium, if it is high enough to give appreciable complex formation. What is more important is that the gap of stability between the lithium and the magnesium complexes is made as small as possible while keeping the values of the constants above 2 log units. In Fig. 3 we present the values obtained for the lithium and magnesium complexes of o-carboxyphenyliminodiacetate (Fig. 4), which has a coordinating site (O⁻, N, O⁻, O⁻) similar to that of uramildiacetic acid, although it is not such a powerful complexing agent[11]. It can be seen that for concentrations of free ATP of the order of $10^{-2.5}$ M the lithium and magnesium complexes are of equal 'effective' stability and for higher concentrations of ATP the lithium complex actually becomes stronger than the magnesium complex; lithium will then be taken up preferentially by this (O⁻, N, O⁻, O⁻) ligand, although log K'_{Li} at $pH = 7$ is not sufficiently high to ensure the predominance of the complex species.

Other similar examples can be given and although the ligands referred to above do not exist *in vivo*, it is likely that analogous or even more adequate coordinating sites may have developed. The variety of sites provided *in vivo* for the uptake of the various elements and the characteristics of those for calcium and magnesium make this idea more than a simple guess or prediction, see, for example, concanavalin[12].

If we consider proteins as ligands, it is obvious that sites of the kind (O⁻, N, O⁻, O⁻) could have evolved, that they would bind Mg^{2+}, but that this binding would be considerably affected by the concentration of ATP and, finally, that in this complicated situation there could be a further weakening of binding through the influence of added lithium. Now, while a situation in which $(Mg^{2+}) = 10^{-3}$ M and $(ATP) = 10^{-2.5}$ M might be thought to be somewhat artificial in the cytoplasm of cells in general, just such a situation arises in the internal fluids of the adrenal chromaffin granule and it could occur in many other vesicles, for example, in the transmitter vesicles of nerve cells. Thus it could well be that Li^+ is indeed challenging Mg^{2+} and so affecting metabolic rates as diverse as the action of glycolysis to the rates of many ATP-driven transfer proteins.

β-Endorphin as a potent analgesic by intravenous injection

An untriakontapeptide[1] with significant opiate activity from camel pituitary glands was shown to have an amino acid sequence identical to the carboxyl-terminal 31 amino acids of β-lipotropins[2,3]. The peptide, designated as β-endorphin, has recently been synthesised[4], and when administered directly into the brain, it was found[5] to be considerably more potent than morphine in molar basis, and its actions were blocked by naloxone. Other peptides related to β-lipotropins have also been shown to possess *in vitro* opiate-like activity[6-9]. We report here the analgesic effects of β-endorphin when it is injected intravenously.

Male ICR mice weighing 25–30 g (Simonson Laboratories) were used in all the experiments. β-Endorphin was synthesised as described previously[4]. Naloxone HCl was a gift from Endo Laboratories and morphine sulphate was purchased from Mallinckrodt Chemical Works. The antinociceptive or analgesic

Fig. 1 Antinociceptive effects following the intravenous injection of β-endorphin in (a) the tail-flick test and (b) hotplate test, and its blockage by naloxone. Mice, 6–7 per group, were injected intravenously with 8.2 (△), 14.5 (□), and 20.1 (○) mg kg⁻¹ of β-endorphin at 0 time. Naloxone HCl (1 mg kg⁻¹) (●) was injected subcutaneously 5 min before the intravenous injection of β-endorphin. 'Percentage' antinociceptic effect was calculated[12] as $[(T_1 - T_0)/(T_2 - T_0)] \times 100$, where a control latency (T_0) was obtained from the mean of two latencies determined before drug injection: test latencies (T_1) were determined at various times after injection for each animal; the cutoff times (T_2) for the tail-flick test and hotplate test were 7 and 60 s, respectively. The vertical bars indicate the s.e.m.

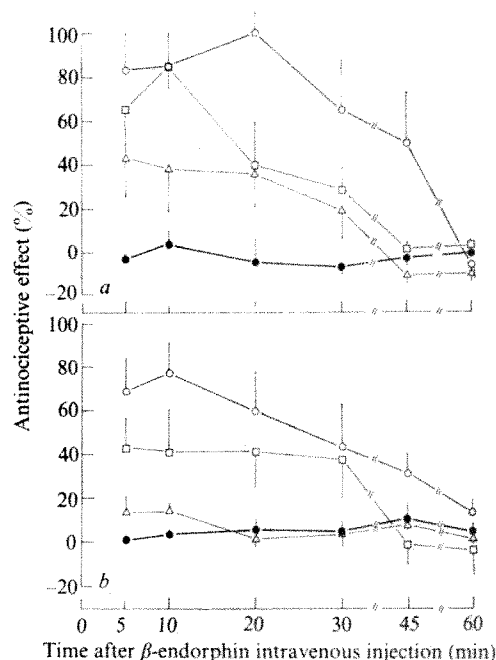
Time after β-endorphin intravenous injection (min)


Fig. 2 Comparison of antinociceptive effects of β-endorphin (●) and morphine (○) in tail-flick test (*a*) and hotplate test (*b*). After control latency was obtained before the drug injection, groups of mice, 6–10 in each, were injected intravenously with various doses of β-endorphin or morphine sulphate and the antinociceptive effect was determined 10 min after drug injection. The values in the figure are median antinociceptive dose (ED_{50}) in mg kg^{-1} and the 95% confidence limits are shown in the parentheses. When the ED_{50} values are expressed on the molar basis, the ED_{50} of β-endorphin is 2.7 μmol kg^{-1} and of morphine 11.4 μmol kg^{-1} in the tail-flick test. The ED_{50} of β-endorphin is 3.5 μmol kg^{-1} and of morphine 11.1 μmol kg^{-1} in the hotplate test.

properties of β-endorphin and morphine were assessed by both the hotplate[10] and the tail-flick[11] methods. β-Endorphin and morphine sulphate were injected intravenously into the tail vein in a volume of 0.01 ml per g body weight. The extent of analgesia or antinociceptive response was expressed as 'percentage antinociceptive effect' (see ref. 12).

With a twofold increase in latency of reaction times as a quantal index of inhibition, the median antinociceptive dose (ED_{50}) and 95% confidence limits were calculated according to the method of Litchfield and Wilcoxon[13].

β-Endorphin administered at intravenous doses of 8.2, 14.5 and 20.1 mg kg^{-1} produced a dose-related inhibition of both the tail-flick and the hotplate response of mice to nociceptive stimuli (Fig. 1). These effects lasted 30–60 min, depending on the dose used, and seemed to be shorter than the duration of β-endorphin when applied centrally[5]. Pretreatment of mice with naloxone HCl (1 mg kg^{-1}, subcutaneously) 5 min before the injection of 20.1 mg kg^{-1} of β-endorphin completely eliminated the inhibitory effect of β-endorphin on the tail-flick and hotplate responses. Thus, in two tests for antinociceptive activity, β-endorphin injected intravenously was as effective as when it was administered directly into the brain.

The percentage of mice which were analgetic after intravenous injection of various doses of β-endorphin and morphine, and their ED_{50} values with 95% confidence limits are given in Fig. 2. The ED_{50} values expressed in mg kg^{-1} of β-endorphin were about 2–3 times higher than that of morphine. When the potency was compared on a molar basis, β-endorphin was ~ 3–4 times more potent than morphine. We have previously shown that β-endorphin was ~ 18–33 times more potent than morphine when applied centrally[5]. Since the molecular weight of β-endorphin is ~ 10 times higher than morphine, it is likely that the lower potency ratio of β-endorphin to morphine when they are applied peripherally is due to the relatively poorer penetration of β-endorphin into the brain. In addition, a different rate of degradation after peripheral administration is a possible factor.

We have shown that β-endorphin can produce analgesia when administered intravenously and the analgesic effect can be eliminated by pretreatment with naloxone. This work was

Comparative study on analgesic effect of Met^5-enkephalin and related lipotropin fragments

Hughes *et al.*[1] have reported the isolation and structure of two pentapeptides from porcine brain with opiate agonist activity in isolated systems. The structure of one of these peptides, Met^5-enkephalin, is identical with the sequence of pituitary β-lipotropin (β-LPH) between residues 61–65 (refs 2–4). To prove the biological correlation of brain enkephalin and pituitary β-LPH, a series of lipotropin fragments, LPH-(61–69)-[5], LPH-(61–76)-[6] and LPH-(61–91)-peptides[7–10], have been isolated and shown to have opiate agonist activity *in vitro*. Only few and controversial data have been available so far on the analgesic effect *in vivo* of the above or similar lipotropin fragments. Enkephalins have recently been reported to induce analgesia *in vivo*[11,12]. Our preliminary data[5,13], however, seemed to contradict these observations, rather suggesting that some larger fragment(s) of β-LPH may have analgesic properties. We have therefore compared the analgesic effects of Met^5-enkephalin and some lipotropin fragments containing the complete structure of Met^5-enkephalin at their NH$_2$-terminus. The results show that the *in vivo* effect is a function of the length of the peptide chain, Met^5-enkephalin being the least and LPH-(61–91)-peptide the most potent. During the preparation of this paper we have become aware of the recent observation of Bradbury and coworkers[10,14] on a strong analgesic activity of LPH-(61–91)-peptide.

Met^5-enkephalin was synthesised as described previously[5]. LPH-(61–79)-peptide was obtained by plasmin cleavage of porcine β-LPH[15–17]. LPH-(61–91)-peptide was isolated from a crude adrenocorticotropic hormone preparation by high voltage paper electrophoresis at pH 6.5 (ref. 9). The *in vitro* opiate agonist activity of the fragments was determined on longitudinal muscle strip of guinea pig ileum[18]. For the *in vivo* assay the classical tail-flick technique was used according to D'Amour and Smith[19]. The tail of male CFY rats was exposed to a radiant heat and the latency of tail withdrawal measured automatically with the accuracy of 0.1 s. The cutoff time was 15 s. All the substances studied were dissolved in saline and administered intra-

cerebroventricularly as described by Chermat and Simon[20], in a volume of 20 μl.

In the *in vitro* assay the potency order was found to be as follows: LPH-(61–91)-peptide=LPH-(61–65)-peptide> LPH-(61–69)-peptide=LPH-(61–79)-peptide (Table 1). The 70–90% inhibitory effect of these fragments could be reversed by 100 nM naloxone.

Using the schedule described by Belluzzi *et al.*[11] for measurement the analgesic effect of peptides—that is, measuring the latency time every 2 min for 10 min—the prolongation of the reaction time was moderate for all the materials studied, including morphine. In addition, the effect of enkephalin was short lasting, subsiding 6–8 min after application (Fig. 1*a*).

This type of *in vivo* effect significantly differs from that caused by either morphine or larger lipotropin fragments since the maximal effect of the latter compounds did not develop within such a short period of time. As Fig. 1*b* shows, using another time schedule—that is, controlling the tail withdrawal reaction for 2 h—a marked analgesic activity was obtained for morphine, LPH-(61–91)- and LPH-(61–79)-peptides, but only a moderate and transitory prolongation of the tail-flick reaction could be achieved by Met⁵-enkephalin. The three stronger analgesic compounds were characterised by a slow onset of action which reached a plateau at 15–30 min after administration and lasted for 60–120 min. Their activity could be antagonised by subcutaneously administered naloxone at a dose of 2 mg kg⁻¹, 30 min before intracerebroventricular treatment.

The *in vitro* and *in vivo* opiate agonist activities of Met⁵-

Fig. 1 Time–response curves for the analgesic activities of morphine and β-LPH fragments administered intracerebroventricularly to rats. Abscissa: time elapsed before (−) and after intracerebroventricular administration of materials (at time 0). Latency time was measured either every 2 min (*a*) or using longer intervals between the measurements as indicated on the scale (*b*). □, Morphine 33 nmol per animal ($n = 20$); ○, LPH-(61–91)-peptide 0.8 nmol per animal ($n = 6$); ●, LPH-(61–65)-peptide 670 nmol per animal ($n = 23$); ×, saline 20 μl per animal ($n = 21$) for *a*; and □, morphine 33 nmol per animal ($n = 19$); ○, LPH-(61–91)-peptide 0.8 nmol per animal ($n = 6$); ▲, LPH-(61–79)-peptide 40 nmol per animal ($n = 5$); ●, LPH-(61–65)-peptide 670 nmol per animal ($n = 10$); ×, saline 20 μl per animal ($n = 16$) for *b*, respectively.
Table 1 Opiate agonist potencies of porcine β-LPH fragments in longitudinal muscle strip of guinea pig ileum

Fragment	Relative agonist potencies*	Statistical evaluation†
LPH-(61–65)-peptide	1 ($n = 4$)	—
LPH-(61–69)-peptide	0.51 ± 0.12 ($n = 4$)‡	$P < 0.05$
LPH-(61–79)-peptide§	0.42 ± 0.06 ($n = 7$)	$P < 0.005$
LPH-(61–91)-peptide§	1.37 ± 0.16 ($n = 4$)	NS

*Potency ratios were calculated from ID_{50} values. The dose–response curves for the peptides were parallel.

†The statistical comparison was based on the ID_{50} values, using the unpaired *t* test.

‡Mean ± s.e.m. values are listed; the numbers of experiments are in parentheses.

§Guillemin *et al.*[6] and Li and Chung[7] have proposed to designate LPH-(61–76)-, LPH-(61–77)- and LPH-(61–91)-peptides as α, γ and β endorphins, respectively. Considering that LPH-(61–79)-peptide also occurs in the pituitary gland (unpublished results), and also that it is closely similar to γ endorphin, we propose to designate it as δ endorphin.

enkephalin (Table 1, Fig. 1) indicate that the molecule contains all the essential residues for the interaction with the opiate receptors. The relative inefficiency and short duration of the *in vivo* effect induced by Met⁵-enkephalin may be due to its rapid degradation by brain enzymes, as also suggested by Belluzzi *et al.*[11]. The more pronounced and prolonged analgesic effect obtained with LPH-(61–79)-peptide strongly supports this view (Fig. 1*b*). LPH-(61–79)-peptide is less potent than Met⁵-enkephalin on longitudinal muscle strip of guinea pig ileum. Consequently the function of the COOH-terminal portion (residues 66–79) of the molecule in increasing the *in vivo* analgesic effect of the peptide may be the protection of the active site (residues 61–65) against the proteolytic enzymes of the brain. A similar protecting role has been attributed to the COOH-terminal portion of adrenocorticotropic hormone (residues 25–39)[21,22]. Among the fragments studied, LPH-(61–91)-peptide showed the highest opiate agonist activity *in vitro* (Table 1). This finding, together with the extremely high *in vivo* analgesic effect of this fragment (at least 50 times higher than that of morphine), suggests that additional receptor binding site(s) may be present within residues 80–91 of the molecule.

Our *in vivo* results and also their explanation seem to be in agreement with the recent data of Bradbury *et al.*[10] on the *in vitro* receptor-binding properties of similar fragments.

We thank Dr T. Lang for encouragement, and Drs J. Borsy, G. Cseh and L. Tardos for discussions.

Selective activation of the mesocortical DA system by stress

IT is now well established that an important system of dopaminergic (DA) neurones innervates various parts of the cerebral cortex in the rat and other species[1–3]. In contrast to noradrenergic (NA) terminals which are widely distributed in this structure, the DA terminals are mainly confined to deep layers, particularly in the frontal, the cingular and the entorhinal areas[4,5]. The results of lesion studies demonstrated that the terminal endings in the frontal cortex originate from the A10 group of DA cell bodies localised in the mesencephalon[6–8]. This group also contains the cell bodies of the classical mesolimbic DA system projecting to the tuberculum olfactorium, the nucleus accumbens, the nucleus of the stria terminalis, and the amygdala[9]. The DA terminals found in the cingulate and entorhinal areas of cortex may originate mainly from the A9 group of DA neurones[6–8]. This group gives rise to the well known nigrostriatal DA system which is implicated in extrapyramidal processes. Its degeneration is in part responsible for some of the symptoms seen in Parkinsonian patients. Little is yet known about the functions of the mesocortical and mesolimbic DA pathways. Electrocoagulation or 6-hydroxydopamine (6-OHDA)-induced lesions of the ventral tegmental area, containing the A10 group, produce a syndrome characterised by "locomotor hyperactivity, serious impairment in tests requiring inhibition of a previously learned response, facilitation of approach learning and of active avoidance and hypoemotivity"[10,11]. Various workers have suggested that the antipsychotic effects of neuroleptics are in part related to the blockade of postsynaptic DA receptors localised in areas innervated by the mesolimbic and mesocortical DA systems[12,13]. It seems important to establish whether neurones of these two DA systems correspond to an homogeneous population of cells with similar functional characteristics. We have therefore explored this problem in the rat by examining the reactivity of the mesocortical and mesolimbic DA pathways as well as that of nigrostriatal DA system to stress induced by electric foot shocks. Our results suggest that the mesocortical DA system is selectively activated by this stress.

Groups of male Charles River rats of the Sprague–Dawley strain, kept in a controlled environment (24 °C, 60% humidity, alternate cycles of 12 h light—0700–1900—and 12 h darkness 1900–0700) and receiving food and water ad libitum were injected at 1400 with α-methylparatyrosine (200 mg kg⁻¹ intraperitoneally), an inhibitor of catecholamine (CA) synthesis. Some of them then received electric foot shocks 10 min later, using a procedure previously described[14]. Others were used as controls. All animals were killed 30 min after administration of the synthesis inhibitor. Changes in CA concentrations were estimated in the medial part of the frontal cortex, the nucleus accumbens and the tuberculum olfactorium, and in the striatum. Since the two first areas are relatively poor in DA or consist of only small amounts of tissue, they were dissected precisely from frozen frontal slices (500 μm thick) using the microdisk technique originally described by Palkovits[15]. Particular care was taken to punch out areas rich in DA fibres

and 3H-DA uptake sites in the medial part of the frontal cortex[8] between planes 9,800 and 12,800 μm; the beginning of the striatum at 9,800 μm according to the atlas of König and Klippel[16] was used as a landmark. The nucleus accumbens was also punched out with a tube sharpened at the extremity (0.8 mm diameter) from two slices delimited by the 9,800- and 8,800-μm planes. Pooled microdisks of tissues corresponding to each area were sonicated in 80 μl of 0.1 N perchloric acid and 0.01 N thioglycollic acid solution. After centrifugation, DA and NA were isolated from the supernatant on alumina microcolumns[17], and measured using the sensitive radioenzymatic microassay of Gauchy et al.[17]. Pellets were dissolved in 0.1 N NaOH for protein estimations[18]. Since the tuberculum olfactorium and the striatum contain large amounts of DA, they were dissected at 4 °C and the amine was isolated by ion-exchange chromatography on Amberlite CG50 and estimated spectrofluorimetrically[14]. To compare the results obtained by the two procedures, in one experiment, DA was estimated radioenzymatically in two microdisks punched out in the mediolateral part of the striatum from two slices (500 μm thick) delimited by the 8,500- and 7,500-μm planes.

Changes in the rate of disappearance of CA after synthesis inhibition provide reliable indications of modifications in the rate of amine utilisation. The electric foot shock stress did not affect the rate of DA utilisation either in the whole striatum or in its mediolateral part, since DA levels were identical in control and stressed animals (Fig. 1.) Similar observations were made in the tuberculum olfactorium. In the nucleus accumbens, however, which is another structure innervated by the mesolimbic DA system, the utilisation of DA was accelerated as indicated by the 25% decrease in DA levels in tissues from stressed animals when compared with those of respective controls (Fig. 1). The stress effect was much more striking in the
Fig. 1 Effect of 20-min electric foot shock stress on the utilisation of DA in structures innervated by the nigrostriatal or the mesolimbic DA pathways. DA was estimated spectrofluorimetrically (total striatum, tuberculum olfactorium) or radioenzymatically (striatal microdisks, nucleus accumbens) 30 min after the injection of α-methylparatyrosine (200 mg kg⁻¹, intraperitoneally) in tissues of control and stressed rats. The stress was applied 10 min after the injection of inhibitor. In the radioenzymatic assay, α-methyldopamine is measured concomitantly with DA. However, α-methyldopamine formed from α-methylparatyrosine represented less than 10% of DA levels 30 min after the inhibitor injection (A. Chéramy, personal communication). Numbers in bars represent absolute mean vaues of DA (ng per mg protein). Data expressed as % of respective control values are the mean ± s.e.m. of results obtained with groups of 6 rats. P < 0.02 when compared with respective controls. DA levels in animals not treated with α-methylparatryrosine were for total striatum, striatal microdisks tuberculum olfactorium and nucleus accumbens: 90.0 ± 6.0 ng mg⁻¹, 75.0 ± 5.0 ng mg⁻¹, 22.3 ± 2.1 ng mg⁻¹ and 79.1 ± 7.0 ng⁻¹ respectively.
Fig. 2 Effects of a 20-min electric foot shock stress on the utilisation of DA in the frontal cerebral cortex of normal rats and of animals deprived of cortical NA innervation (NA deprived). Selective degeneration of ascending NA pathways was induced by local 6-OHDA injections 12 weeks before the stress experiment. All rats were submitted to the 20-min stress situation 10 min after the injection of α-methylparatyrosine (200 mg kg^{-1} intraperitoneally). DA and NA levels were estimated radioenzymatically in the frontal cerebral cortex 30 min after the inhibitor injection (numbers in bars represent the absolute mean values of NA and DA expressed as pg per mg protein). Data expressed as % of respective control values are the mean ± s.e.m. of results obtained with groups of six rats. In rats deprived of noradrenergic innervation, cortical NA levels were less than 10% those of controls. $P < 0.001$. Cortical DA and NA levels in normal rats not treated with α-methylparatyrosine were 720 ± 30 pg mg^{-1} and 950 ± 100 pg mg^{-1}.

frontal cerebral cortex, in which a 60% reduction in DA levels was observed in animals submitted to electric foot shocks (Fig. 2). The short period of stress did not affect the rate of NA utilisation in this structure.

The effect of stress on the mesocortical DA neurones was further studied in rats deprived of a NA innervation to the cerebral cortex. For this complementary experiment, the ascending NA systems were destroyed by a local microinjection of 6-OHDA (2 μg in 1 μl of isotonic saline solution) made laterally to the pedunculus cerebellaris superior[1], 12 weeks before the stress experiment. Two groups of rats were injected as before with α-methylparatyrosine and one of them was exposed to the stress situation. As indicated in Fig. 2, the rate of DA utilisation was accelerated in the stressed rats in a similar manner to that observed in unlesioned animals. As expected, NA could no longer be detected in the frontal cerebral cortex of the lesioned rats. It thus seemed that the stress-induced activation of the mesocortical DA neurones was unrelated to the ascending NA systems.

In previous studies[14], we reported that an electric foot shock stress of long duration accelerated both the utilisation and the turnover of NA in various structures of the brain; the effect being particularly striking in the brainstem. We assumed that these changes in NA metabolism were related to modifications in neuronal activity. The stress of long duration (180 min) did not influence DA utilisation in striatal DA terminals[14]. It is thus not surprising that the 20-min stress used in the present study did not modify the activity of the nigrostriatal DA neurones. In fact, other

stress situations such as exposure to noise or photic stimuli, intense muscular exercises, or exposure to cold, were found to have no effects on DA metabolism in the striatum. In the present study, it was interesting to note that two structures belonging to the mesolimbic DA system did not react similarly to the 20-min stress situation. Indeed DA utilisation was accelerated significantly in the nucleus accumbens but not in the tuberculum olfactorium. This demonstrates that the various DA neurones of the mesolimbic system do not behave similarly. We have already indicated that the DA terminals localised in the medial part of the frontal cortex also originate from the A10 group of DA cell bodies. The dramatic effect of electric foot shocks on the activity of these mesocortical neurones further revealed the heterogeneity of the A10 group. The very pronounced and selective acceleration of DA utilisation in these neurones indicates that the mesolimbic and mesocortical DA systems can be distinguished not only on anatomical grounds but also from a functional point of view. From these results, it is doubtful that the DA terminals present in the various limbic structures and in the frontal cortex originate from the same DA cell bodies. Recent results on the effects of chronic neuroleptic treatments on the synthesis of DA in structures innervated by the mesolimbic and mesocortical DA pathways support the above statements[19]. Indeed, the time curves of the effect of neuroleptics on DA synthesis in the frontal cerebral cortex and in the tuberculum olfactorium + nucleus accumbens were different.

In an earlier study, Bliss and Ailion[20] observed an increase in the content of homovanillic acid (a major DA metabolite) in the whole brains of rats or mice submitted to severely stressful experiments. They suggested that DA neurones could be involved in the cerebral circuit of emotionality. In this context, the high and selective sensitivity of the mesocortical DA neurones to electric foot shock stress revealed in our study is of particular interest. This DA system originates from the "limbic midbrain area" and projects to the frontal cerebral cortex, connected directly and indirectly to the limbic structures. It may be that this mesocortical DA pathway has a critical role in the regulation of emotional states.

Lesion of striatal neurones with kainic acid provides a model for Huntington's chorea

THE symptoms of Huntington's chorea, an hereditary movement disorder, result from degeneration of neurones primarily in the basal ganglia[1]. Several neurochemical abnormalities have been identified in the brains of patients dying with this disorder[2–5], but no animal system with similar neuropathological changes has been described. We now report that the injection of kainic acid into the rat striatum causes neuronal degeneration, neurochemical alterations and behavioural responses resembling Huntington's chorea. This procedure could provide an animal model for the study of the disease.

Systemic administration of monosodium glutamate to immature mice causes degeneration of certain neurones of retina[6] and brain[7]. In brain, neurones with cell bodies in the arcuate nucleus, which selectively accumulates glutamate[8], degenerate whereas axons passing through or terminating in the region are unaffected[9]. The neurotoxic effects of glutamate may be due to its ability to depolarise neurones, for the neurotoxicity of several dicarboxylic and sulphur-containing amino acids structurally related to glutamate correlates with their neuroexcitatory action[10]. In addition, neuronal sensitivity to depolarisation by glutamate is limited to dendrites and soma while axons are unresponsive[11]. Systemic administration of kainic acid, a rigid analogue of glutamate with potent neuroexcitatory effects[12], causes degeneration of central nervous system (CNS) neurones in adult mice; but the attendant high incidence of seizures and death has limited its experimental use[13]. Intracerebral application of excitatory amino acids, however, induces localised neuronal degeneration with neuropathological characteristics similar to that resulting from peripheral administration[14,15].

As the sensitivity of neurones to the toxic effects of neuroexcitatory amino acids may be limited to soma and dendrites, it seemed that an intracerebral injection of kainic acid might cause degeneration of neurones with cell bodies near the injection site, but spare axons terminating in or passing through the area. We have tested the striatum because of its defined neuroanatomy and neurochemistry; it receives a dense innervation from dopaminergic neurones with cell bodies localised in the substantia nigra whereas the striatum itself is populated primarily by small neurones of which cholinergic and GABAergic (gamma aminobutyric acid) neurones are a major component[16]. Accordingly, we have examined the effects of a stereotaxic infusion of kainic acid into the striatum on the neurochemical markers for the intrinsic cholinergic and GABAergic neurones and the dopaminergic terminals in the region.

After anaesthesia with Equi-Thesin (0.6 ml; Jenson–Salisbury Labs), Sprague–Dawley rats (160 g) were positioned in a David Kopf small animal stereotaxic apparatus; and a 0.3-mm Hamilton cannula was inserted into the striatum through a burr hole in the calvarium (coordinates: 7.9 A; 2.6 L; 4.8 V). Drugs dissolved in 1 μl of artificial cerebrospinal fluid (CSF) (titrated to pH 7.4) were infused over 1 min; the cannula was then removed and the scalp
Fig. 1 The activities of tyrosine hydroxylase[23] (open bar), choline acetyltransferase[24] (solid bar) and glutamic acid decarboxylase[25] (striped bar) in the striatum were assayed 48 h after unilateral injection of various amounts of kainic acid (Ka) or α-methylaspartate (α-M-Asp). Results are presented in terms of percentage of the specific activity of the contralateral striatum with s.e.m. indicated. $N = 5$. $*P < 0.001$. $†P < 0.05$.

was apposed with sutures. At various times after treatment, the rats were killed; and the striata were dissected according to the method of Glowinski and Iversen[17].

In initial experiments, the effects of infusion of various amounts of kainic acid (0.1–10 μg) on the neurotransmitter-synthesising enzymes in the striatum were examined 48 h after injection (Fig. 1). With the injection of 0.5 μg, there was a 20% reduction in the activities of glutamic acid decarboxylase (GAD) and choline acetyltransferase (CAT). With increasing doses, there was a progressive reduction in the activities of GAD and CAT whereas the activity of tyrosine hydroxylase (TH) exhibited a dose-dependent increase. Two days after injection of 2 μg of kainic acid, the activities of GAD and CAT were reduced 80% whereas the activity of TH was increased 80%. Doses in excess of 5 μg of kainic acid did not further alter enzyme activities in the striatum but were associated with a high rate of mortality. These changes in enzyme activity were not caused by the injection procedure, for the infusion of 10 μg of α-methyl-aspartate, an analogue of glutamate without neuroexcitatory activity[18], and did not alter significantly the activities of these enzymes. In contrast to the effects of kainic acid, the infusion of copper sulphate (25 μg), a nonspecific toxic agent[19], caused a similar 60–65% reduction in the activities of TH as well as GAD and CAT.

It is possible that the 80% decrease in the activities of CAT and GAD and 80% increase in the activity of TH after injection of 2 μg of kainic acid reflected merely a transient neurochemical adaptation to excessive stimulation of glutamate receptors. To obtain further information, we examined several neurochemical markers for the cholinergic, GABAergic and dopaminergic neurones 10 d after infusion of 2.5 μg of kainic acid (Table 1). The injection elicited a 60–70% decrement in the activity of GAD, the levels of endogenous GABA, the activity of the synaptosomal high affinity uptake process for GABA. Similarly, the activity of CAT, the levels of endogenous acetylcholine and the activity of the synaptosomal uptake process for choline were reduced 60–70%. In contrast, the activity of TH was 50% above control; the levels of endogenous dopamine and the activity of the synaptosomal uptake process for dopamine were not significantly affected by the injection. In addition, the wet weight of the striatum and protein content were not changed by the treatment.

Table 1 Effects of kainic acid on neurochemical parameters of the striatum 10 d after injection

		Injected	Control	Δ
GABAergic neurones				
Glutamic acid decarboxylase	nmol mg^{-1} h^{-1}	4.13±0.8	12.9±0.9	−68*
GABA	nmol mg^{-1}	0.72±0.15	2.16±0.17	−67*
GABA uptake	pmol per mg per 4 min	7.1±1.2	16.5±1.3	−57*
Cholinergic neurones				
Choline acetyltransferase	nmol mg^{-1} h^{-1}	6.0±1	20±1	−70*
Acetylcholine	pmol mg^{-1}	20±4	68±4	−71*
Choline uptake	pmol per mg per 4 min	0.05±0.01	0.12±0.01	−60*
Dopaminergic neurones				
Tyrosine hydroxylase	pmol mg^{-1} hr^{-1}	340±25	232±21	+47*
Dopamine	pmol mg^{-1}	52±4	60±4	−13
Dopamine uptake	pmol per mg per 4 min	3.1±0.3	2.4±0.3	+29
Wet weight	mg	48±2	49±2	−2
Protein	µg per mg tissue	165±9	173±7	−5

Kainic acid (2.5 µg) was injected into the striatum 10 d before killing the rats. The activities of tyrosine hydroxylase[23], choline acetyltransferase[24], and glutamic acid decarboxylase[25] and the levels of GABA[26], acetylcholine[27], dopamine[28] and protein[29] were assayed. The uptake of labelled GABA[30], choline[31], and dopamine[32] was measured in washed P$_2$ fractions prepared from striatum. The contralateral uninjected striatum served as control $N = 6-12$.
*$P < 0.001$.

Some of the GABAergic neurones with cell bodies in the striatum provide an inhibitory pathway innervating the dopaminergic cell bodies in the substantia nigra[16,20]. In rats receiving a unilateral infusion of 2.5 µg of kainic acid in the striatum 1 week before death, the levels of endogenous GABA were reduced 67±3% ($N=5$; $P<0.001$) in the ipsilateral substantia nigra. In contrast, the activity of tyrosine hydroxylase was not significantly altered in the substantia nigra on the injected side. Thus, the striatonigral GABAergic pathway seems to be affected selectively by the striatal injection of kainic acid.

Although these marked neurochemical alterations 10 d after injection of kainic acid suggest specific degeneration of cholinergic and GABAergic neurones intrinsic to the striatum, histological evidence is required. Therefore histological sections stained with cresyl violet were prepared from whole forebrain at the level of the striatum of animals

Fig. 2 Micrographs of rat striatum showing the loss of neurones on the side injected with 2.5 µg of kainic acid (*b*) compared with the contralateral side (*a*) as control. Ten days after injection, the animals were killed by aortic perfusion with buffered formaldehyde. Sections (30 µm) were stained with cresyl violet. Neuronal perikarya are markedly reduced in number on the injected side which also shows marked gliosis. The lighter areas, which are bundles of internal capsule fibres, are unaffected by the treatment. The bar represents 100 µm.

injected unilaterally with 2.5 µg of kainic acid 10 d before death (Fig. 2). Around the site of injection there was generalised loss of approximately 95% of neuronal perikarya in a radius of 1.5 mm, with a gradation in loss with increasing distance. Thus, the lesion involved nearly the entire head of the caudate putamen but did not affect the tail of the caudate or the globus pallidus (our work in preparation). Although the needle track was visible, there was no evidence of inflammatory changes or necrosis at the injection sites, but there was a generalised increase in the number and prominence of glia. The overall structure of the striatum containing the bundles of internal capsule fibres seemed to be unchanged except for the loss of neurones.

The striking behaviour of animals treated with a unilateral injection of kainic acid in the striatum demonstrates the physiological significance of the lesion. For up to 24 h after injection, the rats exhibited marked rotatory behaviour away from the side of the injection, which would be consistent with the neuroexcitatory effects of the drug in the striatum[15]. Two days after injection, however, they reversed the direction of rotation towards the side of the injection. The ipsilateral rotatory behaviour, which persisted up to 10 d after injection, is similar to that produced by lesions in the dopaminergic nigrostriatal pathway[21]. Thus, the lesion caused by kainic acid in striatal neurones, which are presumably postsynaptic to the dopaminergic terminals[16,22], results in a behaviour similar to that induced by ablation of the dopaminergic innervation to the striatum.

The striatal lesions produced by kainic acid have particular relevance to Huntington's chorea because the major site of neuropathological change in this disorder is the striatum, where a marked loss of intrinsic neurones and gliosis occurs[1]. There are considerable decreases in the neurochemical markers for the cholinergic and GABAergic neurones in the striatum whereas the dopaminergic innervation to the region is relatively unaffected; in addition, there is a selective reduction in the activity of GAD and levels of GABA in the substantia nigra[2-5]. The neurochemical, histological and behavioural changes resulting from striatal infusion with kainic acid are remarkably similar to those observed in Huntington's chorea. Thus, lesions of the rat striatum produced with kainic acid may provide a useful animal model for Huntington's chorea, in which the biochemical, electrophysiological and pharmacological sequelae of the loss of striatal cholinergic and GABAergic neurones can be examined.

We thank Robert Zaczek for technical assistance and Dr Michael Kuhar and Naomi Taylor for doing the histological

studies. This work was supported by a grant to J.T.C. from USPHS.

Evidence for a role of central serotonergic neurones in digitalis-induced cardiac arrhythmias

EVIDENCE indicates that digitalis drugs administered intravenously increase central sympathetic outflow and that this in turn results in cardiac arrhythmias[1–6]. The central nervous system transmitter(s) that mediates this effect is not known. According to Saito *et al.*, noradrenaline, the primary transmitter studied so far, is not involved in the case of guinea pigs[7]. 5-Hydroxytryptamine (5-HT) however, may be an important chemical mediator regulating central sympathetic outflow[8,9], and it is involved in the respiratory arrest induced in rats by intravenous administration of digitoxigenin[10]. We now report evidence that suggests that brain 5-HT is involved in digitalis-induced cardiac arrhythmias.

Cats (1.6–3.6 kg) were anaesthetised with alpha chloralose (70–80 mg kg^{-1} intravenously) and artificially ventilated with room air. The femoral artery and vein were catheterised for recording blood pressure and administering drugs, respectively. Rectal temperature was maintained between 36° and 38 °C by warming the cat with radiant heat. The electrocardiogram and the arterial blood pressure were recorded. The digitalis preparation, deslanoside, was administered by a continuous intravenous infusion of 2 µg kg^{-1} min^{-1}. Doses necessary to produce the following endpoints were obtained: ventricular arrhythmia, ventricular tachycardia and ventricular fibrillation. The role of brain 5-HT in the arrhythmogenic effects of deslanoside was assessed by determining: (1) the effect of pretreatment with *p*-chlorophenylalanine (PCPA) on the doses of deslanoside

needed to produce ventricular arrhythmias (PCPA was administered as 300 mg kg^{-1} intraperitoneally each day for 3 d before the animals were intoxicated with deslanoside); (2) the effect of 5,7-dihydroxytryptamine (5,7-DHT) on the doses of deslanoside needed to produce ventricular arrhythmias (5,7-DHT was administered as a single dose of either 100 µg kg^{-1} to three cats, or 200 µg kg^{-1} to two cats, into the anterior horn of the left lateral ventricle 8 d before intoxication with deslanoside), and (3) the effect of methysergide as both pretreatment (3 mg kg^{-1} intravenously, 10 min before deslanoside infusion and repeated 45 and 85 min after deslanoside infusion started) and as a treatment (3 mg kg^{-1} intravenously, 1–6 min after a ventricular arrhythmia had been evoked by deslanoside).

To assess the extent and selectivity of the depletion of brain 5-HT by PCPA and 5,7-DHT, the brains of cats intoxicated with deslanoside were removed immediately after the onset of ventricular fibrillation. The brains were placed on ice and the medulla–pons, hypothalamus and superior and inferior colliculi were dissected out, frozen on dry ice and stored at −20 °C until assayed (up to 3 weeks). Biogenic amines, 5-HT and noradrenaline were assayed by a modification of the procedures of Chang *et al.*[11] and Maickel *et al.*[12], as described in detail by Zenker *et al.*[13]. Results are expressed as the mean µg of amine per g of tissue ±s.e.m.

Fig. 1 Effect of methysergide on deslanoside-induced ventricular arrhythmia. *a*, Electrocardiogram (ECG) and arterial blood pressure (BP) tracings before intoxication with deslanoside. *b*, Effects of a cumulative dose of deslanoside (200 µg kg^{-1}) on ECG and BP just before the development of a ventricular arrhythmia. *c*, Deslanoside-induced ventricular arrhythmia. *d*, ECG and BP tracings 2.5 min after 3 methysergide (3 mg kg^{-1}) was administered.
Table 1 Effect of p-chlorophenylalanine, 5,7-DHT and methysergide pretreatment on the capacity of deslanoside to produce ventricular arrhythmias

| Group | No. in each group | Heart rate and blood pressure before deslanoside infusion | | Doses of deslanoside to produce cardiac arrhythmias ($\mu g\ kg^{-1}$) | | |
		Heart rate (beats per min)	Mean blood pressure (mmHg)	Ventricular arrhythmia	Ventricular tachycardia	Ventricular fibrillation
Control	21	193 ± 5.8	136 ± 7.3	165 ± 8.5	178 ± 8.5	212 ± 11.3
p-Chlorophenylalanine pretreatment	7	186 ± 9.8	132 ± 7.8	$238 \pm 22.8^*$	$246 \pm 22.7^*$	$277 \pm 18.6^*$
5,7-Dihydroxytryptamine pretreatment	5	190 ± 6.4	123 ± 16.4	$219 \pm 10.6^*$	$223 \pm 10.4^*$	258 ± 15.1
Methysergide pretreatment	5	$131 \pm 12.3^*$	$96 \pm 7.7^*$	$232 \pm 29.0^*$	$249 \pm 27.5^*$	$317 \pm 35.4^*$

Controls were 12 animals given deslanoside only, three given saline intraperitoneally for 3 d and then intoxicated with deslanoside (to control for p-chlorophenylalanine injections), and six given saline into the anterior horn of the left lateral ventricle and 8 d later intoxicated with deslanoside (to control for the 5,7-DHT injection). Values between the three control groups were not significantly different so the data were pooled.
$^*P < 0.05$ when data are compared with corresponding control data.

of triplicate determinations. Using a Farrand Fluorescent MK-1 spectrophotofluorometer, the fluorescent intensity of the biogenic amines was determined in 1-cm quartz cells.

The pretreatment studies (Table 1) showed that animals given any one of the three agents that interfere with brain 5-HT function required a significantly larger dose of deslanoside to produce ventricular arrhythmias. PCPA and 5,7-DHT inhibit tryptophan hydroxylase and destroy central serotonergic nerves, respectively; animals pretreated with these drugs exhibited a significant decrease in the 5-HT content in all brain regions analysed (Table 2). Depletion

Taken together, these results suggest that central serotonergic neural systems are involved in the central arrhythmogenic effect of digitalis. Central serotonergic neural systems have been demonstrated by some investigators to have an important influence on central sympathetic outflow[8,9,19]. For example, Wing and Chalmers[8] reported that intracisternal administration of 5,6-DHT prevents the increases in arterial blood pressure and heart rate produced by sinoaortic denervation in unanaesthetised rabbits. This suggests that activity in central serotonergic nerves increases central sympathetic outflow. Wing and Chalmers did not

Table 2 Effect of p-chlorophenylalanine and 5,7-DHT on 5-HT and noradrenaline content of selected brain regions

| Group | No. in each group | Brain region | | | | | |
| | | Medulla–pons | | Hypothalamus | | Colliculi | |
		5-HT ($\mu g\ g^{-1}$)	Noradrenaline ($\mu g\ g^{-1}$)	5-HT ($\mu g\ g^{-1}$)	Noradrenaline ($\mu g\ g^{-1}$)	5-HT ($\mu g\ g^{-1}$)	Noradrenaline ($\mu g\ g^{-1}$)
Controls (no drug)	6	0.73 ± 0.03	0.91 ± 0.05	1.53 ± 0.04	1.30 ± 0.04	0.87 ± 0.03	0.28 ± 0.02
Animals intoxicated with deslanoside	6	0.75 ± 0.03	0.85 ± 0.04	1.53 ± 0.04	1.20 ± 0.04	0.86 ± 0.03	0.31 ± 0.03

$^*P < 0.05$ when data are compared with either the control group or the animals intoxicated with deslanoside.

of 5-HT content with these drugs seemed to be selective, as no significant changes in noradrenaline were observed.

Deslanoside had no significant effect on brain 5-HT levels (Table 2). This was not unexpected, for treatments that enhance central serotonergic neural activity do not alter 5-HT levels although they increase turnover[14].

We tested methysergide for antiarrhythmic effects because this drug rapidly antagonises 5-HT receptors after intravenous administration[15]. It was administered intravenously (as a bolus of 3 mg kg⁻¹) to three control cats with a sustained ventricular tachycardia induced by deslanoside. In each cat, methysergide converted the existing ventricular arrhythmias to sinus rhythm (Fig. 1).

Pretreatment with PCPA and 5,7-DHT had no significant effect on baseline heart rate and arterial pressure. Pretreatment with methysergide resulted in a significant reduction in both heart rate and arterial pressure (Table 1).

We have also found[16] that doses of deslanoside that produce lethal ventricular arrhythmias significantly increase 5-hyrdoxyindoleacetic acid tissue concentration and tryptophan hydroxylase activity in the hypothalamus, amygdala and colliculi. This indicates that deslanoside produces biochemical changes in the central serotonergic system that are consistent with the drug activating serotonergic neurones[17]. We have also found[18] that electrical stimulation of midbrain raphe areas causes similar kinds of arrhythmias and biochemical changes (changes in 5-hydroxyindoleacetic acid and tryptophan hydroxylase activity), as does deslanoside.

observe drastic changes in baseline heart rate or arterial pressure with 5,6-DHT, indicating that normal sympathetic outflow may not be greatly affected by depleting brain 5-HT. In the study reported here, no significant changes in these baseline cardiovascular parameters were observed with either 5,7-DHT or PCPA. Thus interference with central 5-HT synthesis or selective degeneration of central 5-HT nerve endings may prevent noxious influences (digitalis overdose or sinoaortic denervation) from deranging central sympathetic outflow without disrupting normal tonic central sympathetic activity.

Absolute sensitivity of rod bipolar cells in a dark-adapted retina

THE visual system of vertebrates mediated by rods is capable of detecting a few quanta of light[1,2]. The work reported here is concerned with the voltage response to flashes of light in individual bipolar cells, to which the rods send their signals and which, in turn, signal to amacrine and ganglion cells. We measured the absolute sensitivity of rod bipolar cells in the dogfish retina. The photoisomerisation of a single rhodopsin chromophore in only one rod out of 100 leads to a response of 1 mV in the bipolar cell.

Intracellular recordings were made in the eyecup preparation of the dogfish, *Scyliorhinus canicula*, dissected in dim red light from animals dark-adapted for at least 3 h. This species has visual receptors which are almost exclusively rods, containing a photopigment[3] with maximum absorbance at 500 nm. The light source was a tungsten–iodine lamp operated from a stabilised d.c. supply and filtered by a bandpass interference filter with peak transmission at 495 nm. The irradiance of the source through the bandpass and heat-absorbing filters was calibrated with a radiometer (Tektronix J16/J6502 radiance probe), and checked by a photomultiplier in single-photon counting mode. Dark adaptation was maintained by using dim test flashes to locate bipolar cells. Cells were penetrated in the region of retina backed by the tapetum lucidum. The responses reported here were obtained with full-field illumination.

The identification of the cells as bipolar cells is based on criteria of depth, waveform and receptive field. The cells were

Fig. 1 Responses of a bipolar cell in the dark-adapted retina of the dogfish *Scyliorhinus canicula* to 18-ms flashes of light of varying intensity. An increase of internal potential (depolarisation) is indicated by an upward deflection. The timing of the flash is shown beneath the superimposed traces. The numbers near each trace represent the number of photons μm^{-2} at 495 nm delivered by the flash. The internal potential of the cell in the dark was -40 mV.
Fig. 2 The relationship between light intensity and peak of the response for the bipolar cell shown in Fig. 1. Note that the scale for light intensity is logarithmic. The three points shown at the lowest light levels were obtained by signal averaging, each point being the average of eight responses.

impaled at depths of 70–100 μm from the vitreal surface of the retina, often in close proximity to a horizontal cell. The response to light flashes (Fig. 1) consists of a depolarisation graded with the light intensity, with a maximum response of up to 30 mV. The response characterised by a phasic peak, which declines to a plateau, is evoked at higher light intensities. This is the response described by Kaneko for bipolar cells, identified by staining with Procion dyes in the retina of the related species, *Mustelis canis*[4]. As in bipolar cells in other retinae, there is an 'off' response which follows the cessation of a long, near-saturating pulse of light[5]. The receptive field for the centre response of these cells is less than 500 μm and in some cells less than 200 μm. An antagonistic effect produced by illumination of the surround is often used to identify bipolar cells; the cells reported here, however, have only a weak centre-surround organisation. There are reasons to suppose that dark adaptation diminishes the effect of the surround[6].

To analyse the sensitivity of the cells, the responses to brief flashes of light were recorded at low light levels in the region over which the response was proportional to intensity, as well as at higher light levels. The small signals evoked by dim lights were averaged by means of a computer. Figure 2 shows the intensity–response curve for the cell whose responses were illustrated in Fig. 1. The line of Fig. 2 fitted to the experimental points is of the form

$$V = V_{max}\frac{I}{I+I_{\frac{1}{2}}} \qquad (1)$$

a hyperbolic relationship between the response, V, and the light intensity, I. For this cell $V_{max} = 17.5$ mV and the half-saturating intensity, $I_{1/2} = 0.06$ photons μm^{-2} per flash. The absolute sensitivity of the cell[7] was determined as the ratio of response to intensity of light, within the range over which the response was proportional to light intensity. The flash sensitivity for this cell was 310 mV photon^{-1} μm^2. The results for other bipolar cells are given in Table 1. There was considerable variation in sensitivity and $I_{1/2}$ values among cells, but the flash sensitivity consistently exceeded 100 mV photon^{-1} μm^2, provided that V_{max} was greater than 8 mV.

To convert these figures to the voltage response that would be produced by the photoisomerisation of a single rhodopsin

Table 1 Flash sensitivity of rod bipolar cells and the semi-saturation value of light intensity, $I_{1/2}$

V_{max} (mV)	Flash sensitivity (mV photon^{-1} μm^2)	(mV rod per isomerisation)	$I_{1/2}$ (isomerisation per rod)
17.5	310	103	0.18
23.8	330	110	0.42
21.8	200	67	0.33
14.1	373	124	0.55
13.8	137	46	1.20
25.5	170	57	0.63
8.1	476	159	0.18
9.3	228	76	0.55
18.5	323	108	0.19
Mean	283	95	0.47

For some cells, the slope of the intensity–response curve near $I_{1/2}$ was significantly less steep than would be indicated by equation (1). The extent of the deviation may be gauged by comparing the flash sensitivity derived from the response to dim flashes with the value $V_{max}/I_{1/2}$. The internal potential of the cells in the dark ranged between -40 and -62 mV.

chromophore in each rod, an estimate of the photoisomerisation cross section (also called the effective collecting area[7]) is required. The geometric cross section of *Scyliorhinus* rod outer segments suspended in vitreal fluid is 7.1 μm^2 and their length is 28 μm. On the assumption of a specific axial density[8] for rhodopsin of 0.014 μm^{-1}, a quantum efficiency for photoisomerisation of 0.67 (ref. 9), a reflectivity of the tapetum of 90% (ref. 3) and the further assumption that all the incident light passes into the outer segments, the photoisomerisation cross section would be 3.7 μm^2. This figure takes no account of the fact that some of the light will pass between photoreceptors as well as being scattered by other retinal layers. We therefore tentatively assign a value of 3 μm^2 for the photoisomerisation cross section. This value has been used to derive the flash sensitivities of the rod bipolar cells (given as the response in mV per photoisomerisation in each rod) and to estimate the number of photoisomerisations per rod necessary for half saturation of the response of a bipolar cell. On average, the response is half-saturated when one rhodopsin chromophore is isomerised in just one out of two rods and there is a response of ~ 1 mV in the bipolar cell when there has been one photoisomerisation in one out of 100 rods (Table 1).

Because of their small size, it has not been possible to determine the flash sensitivity of dogfish rods. The highest values reported for flash sensitivities of uniformly illuminated rods were obtained by Fain[10] in *Bufo marinus* (0.68 mV per photoisomerisation) and by Copenhagen and Owen[11] in the snapping turtle (0.72 mV per photoisomerisation). There is no reason to suppose that the rods of dogfish are unusually sensitive. Measurement of the externally recorded receptor potential of the electroretinogram yields a value for the number of photoisomerisations for half saturation similar to that reported for other vertebrate rods[10-14]. It is possible that the isomerisation of a chromophore in a dogfish rod may lead to a somewhat larger voltage change than has been observed in rods of larger diameter. If photoisomerisation produces the same underlying membrane conductance change in all rods, the voltage change produced would then depend on the dimensions of the cell, varying approximately as 1/diameter if the rod were regarded as a short cable. On this basis, the flash sensitivity for dogfish rods might be about 2 mV per photoisomerisation. If rods are electrically coupled[10,11,15], then at low light levels when only a few rods absorb a photon, the voltage response in any one rod will be only a small fraction of what would be obtained in an electrically independent rod.

These measurements allow some deductions about signal transmission between rods and bipolar cells to be made. The dynamic voltage gain in signal transmission is the ratio of the flash sensitivity of the bipolar cell to that of the rods; in this case, yielding a gain of about 50. Schwartz[16] also concluded that there was a large increase in signal amplitude in transmission from cones to bipolar cells in the turtle retina. A dynamic voltage gain of 50 can be compared with a value of

about 3, applicable to a number of conventional chemical synapses[17]. In both cases, it must be assumed that the postsynaptic cell linearly sums the transmitter-modulated conductance increments contributed by all the presynaptic cells which converge on it. The maximum dynamic gain can be specified in terms of the fractional contribution of transmitter-modulated conductance to the total conductance of the postsynaptic cell (and, therefore, does not depend explicitly on convergence). The higher dynamic gain at the rod–bipolar cell synapse remains to be explained.

Identification of actin-binding protein in membrane of polymorphonuclear leukocytes

A NEW protein with a high molecular weight and found in rabbit alveolar macrophages[1], causes actin filaments in sucrose solutions to form a solid gel when warmed to room temperature. With transmission electron microscopy, the actin filaments were observed to be bound into branching interconnecting bundles[2]. The new protein was called actin-binding protein (ABP). Similar consistency changes, which are due to gelation of actin associated with other proteins, have been observed in sucrose extracts of *Acanthamoeba* and glycerol extracts of sea urchin eggs[3,4]. ABP was subsequently isolated from extracts of chronic myelogenous leukaemia (CML) leukocytes[5]. The CML leukocyte ABP had identical properties to the analogous protein isolated from the rabbit alveolar macrophage. The CML leukocyte ABP in the presence of actin produced a gel that structurally resembled the hyaline ectoplasm of a pseudopod. Since particle contact with the phagocytic membrane leads

to generation of a pseudopod, it seemed reasonable that ABP might be associated with the membrane. Using an antibody directed against CML leukocyte ABP coupled with indirect immunological stains, we were able to localise ABP to the cytoplasmic surface of the membrane of normal polymorphonuclear leukocytes.

We prepared[6] rabbit IgG against purified CML leukocyte ABP (Fig. 1). The antibody activity was eliminated by absorption with either purified ABP or intact normal polymorphonuclear (PMN) leukocytes. Furthermore, no cross reactivity was demonstrated in an Ochterlony plate with two different preparations of myosin antiserum. We had noted previously that ABP antibody inhibited the gelation of CML leukocyte extracts as well as of purified leukocyte actin filaments in the presence of ABP[5].

In rabbit alveolar macrophages, contact of an ingestible particle with the cell surface generates more extractable ABP[2]. These findings suggest that ABP might be associated with the plasma membrane of phagocytes. To verify whether human leukocyte ABP is found in PMN leukocyte membranes, we prepared phagolysosomes after allowing the cells to phagocytose opsonised lipopolysaccharide-coated paraffin oil droplets[7]. The phagolysosome forms by fusion of lysosomal granule membranes with inverted sections of the plasma membrane. These 'inside-out' membrane preparations were exposed to purified anti-ABP IgG or normal rabbit IgG and then treated with goat anti-rabbit IgG (γ chain) conjugated with fluorescein isothiocyanate (FITC; Hyland Laboratory, Costa Mesa, California). Diffuse membrane fluorescence was observed with the anti-ABP IgG (Fig. 2). Since the plasma membrane Fc receptors were hidden inside these phagolysosomes, there was no observable fluorescence with normal rabbit IgG. Staining was also eliminated from ABP antibodies by absorbing the antibody with purified ABP or intact PMN leukocytes.

The nonspecific fluorescence of intact cells prevented us from using the same technique to identify ABP on their plasma membranes. For this study, we used an immunoperoxidase stain[8] which eliminated the problem. Peripheral

Fig. 2 Phagocytic vesicles were incubated with ABP IgG for 20 min at 25 °C. The vesicles were washed three times in Krebs–Ringer phosphate, pH 7.4, and suspended in goat anti-rabbit IgG (γ chain) conjugated with fluorescein for 20 min; then they were washed again. The resulting phagocytic vesicle was observed after settling on to a glass coverslip using a Zeiss epiilluminator with a FITC interference filter, 450 dichroic mirror, 53 barrier filter, and a $\times 100$ objective.

Fig. 1 Immunodiffusion of human leukocyte ABP (centre well) against anti-ABP IgG (1) and against 1:2 dilution of the anti-ABP IgG (4); two different anti-leukocyte myosin antisera (5 and 6); anti-ABP antisera absorbed with intact PMN leukocytes (2); and anti-ABP antisera absorbed with purified ABP antigen (3).

blood leukocytes were treated with peroxide and methanol to block endogenous peroxidase. The cells were incubated with anti-ABP IgG, washed, and incubated with goat anti-rabbit IgG conjugated with horseradish peroxidase and washed again. The fixed dried smears were then stained for peroxidase. Those cells incubated with anti-ABP IgG had maximal reactivity at the cell margins (Fig. 3). No

staining of PMN leukocytes occurred with a normal IgG nor of lymphocytes or monocytes with the specific antibody.

Actin, myosin and ABP have been identified by polyacrylamide gel electrophoresis in enriched rabbit alveolar membrane fractions[9]. Whether ABP is an integral protein or largely associated with surfaces of the leukocyte membrane is not ascertainable from our studies. It is, however, tempting to believe that ABP by its membrane location could transduce surface recognition of particles into mechanical events, leading to actin polymerisation and the generation of pseudopodia.

Transient kinetics of (Na+ +K+)-ATPase studied with a fluorescent substrate

WE describe experiments, with a purified (Na[+]+K[+])-ATPase, designed to investigate details of the enzymatic process that couples ATP hydrolysis to the active transport of Na[+] and K[+] ions. We have found that formycin triphosphate[1-3] (FTP), an analogue of ATP previously used in studies of myosin ATPase[4], is a substrate for the (Na[+]+K[+])-ATPase, and that the binding of FTP or of formycin diphosphate (FDP) to the enzyme is accompanied by a two- to threefold enhancement of nucleotide fluorescence. The change in strength of the fluorescent signal has allowed us to measure equilibrium binding of the nucleotides to the enzyme, and using stopped-flow fluorimetry we have been able to measure the rates of binding and release. FTP and FDP bind with a high affinity and may be displaced by excess ATP or by K[+] ions. During turnover, at least with FTP concentrations up to 24 μM, the FDP is released (or its fluorescence is quenched) before the rate-limiting step of the overall reaction, both in the presence and absence of K[+] ions. When turnover is prevented by the absence of magnesium, the enzyme is still able to change its conformation according to whether Na[+] or K[+] is the predominant alkali-metal ion[5]. Because the Na and K conformations have different nucleotide affinites, we have been able to measure the rates of the conformational changes by monitoring the decrease or increase in fluorescence associated with the net release or binding of nucleotide. Finally, the effects of alterations in FTP concentration on the time course of the fluorescence changes have provided a clue to the non-phosphorylating role of ATP.

All experiments were done at about 21 °C with a (Na[+]+K[+])-ATPase from pig kidney, purified by the simpler method of Jørgensen[6]. The enzyme had a specific activity of about 17 μmol
Fig. 1 Binding of FTP to (Na[+]+K[+])-ATPase as a function of FTP concentration. (Na[+]+K[+])-ATPase prepared from pig kidney by the simpler procedure of Jørgensen[6] was washed to remove traces of ATP and suspended at 60 μg ml[-1] in 2.5 ml of a solution containing NaCl 50 mM, EDTA (Tris salt, pH 7.7) 5 mM, and FTP (triethylamine salt) as indicated. ATP was added in 2 μl steps to give a final concentration of 25 μM. Fluorescence was measured at room temperature in a Farrand fluorimeter modified to allow additions to be made during continuous stirring and recording. Fluorescence was excited at 310 nm, and the light emitted at 380 nm was measured using 10-nm slits. A Wratten 18A stray-light filter was placed after the excitation monochromator, and a Schott W.G.365 stray-light filter before the emission monochromator. With 4 μM FTP, about half of the emitted light came from intrinsic protein fluorescence and scattering. Inset: reduction in fluorescence (ΔF) produced by the addition of ATP. Note that a second addition caused no further change, and that with 4 μM FTP, ΔF was only about 4% of total 380-nm emission, because the FTP initially bound to the enzyme was only a small fraction (2–3%) of the total FTP in the cuvette.

ATP hydrolysed per mg protein min[-1] at 37 °C, and well over 99% of the activity was sensitive to ouabain. FTP binding to the enzyme was measured by mixing FTP and enzyme in the fluorimeter cell, in the presence of EDTA, and then measuring the reduction in fluorescence when the bound nucleotide was displaced by a large excess of ATP. Measurements of binding at several FTP concentrations gave the saturation curve shown in Fig. 1 and a calculated dissociation constant of 1.1 μM. A similar experiment with FDP gave a dissociation constant of 4.8 μM. ATP competed effectively with both FTP and FDP, and the calculated inhibition constant was 0.15 μM, which is similar to published values of 0.22 μM (ref. 7) and 0.12 μM (ref. 8) for the ATP dissociation constant.

Fluorescence enhancement could also be reversed by the addition of K[+], Tl[+], Rb[+], NH[4][+] and Cs[+], almost certainly because these ions cause dissociation of bound nucleotide[7]. Figure 2 shows the results of an experiment in which FDP was displaced from the enzyme by titration with KCl; virtually identical results were obtained with FTP. In the presence of 133 μM Na[+], 50% dissociation of nucleotide was obtained with a K[+] concentration of 140 μM.

The kinetics of FTP binding and FDP release during enzyme turnover were studied with the stopped-flow fluorimeter. Enzyme from one syringe was mixed with Mg[2+] and FTP from another, in the presence of Na[+] and Tris buffer. Figure 3 shows the results of two experiments with different time scales. Mixing was followed by (i) a very rapid rise in fluorescence, (ii) a rapid fall in fluorescence, with a rate constant of 14 s[-1] in Fig. 3a, (iii) a period of low fluorescence, and (iv) a final rise in fluorescence. The initial very rapid rise in fluorescence cannot be seen in Fig. 3 because of the time constant chosen. It almost certainly represents FTP binding, and it gives a calculated second-order rate constant of 2–8 × 10[7] M[-1] s[-1]; the rate was too fast to allow more precise determination. The rapid drop in fluorescence is most simply attributed to FDP release from
Fig. 2 Dissociation of FDP from $(Na^+ + K^+)$-ATPase by the addition of K^+ ions. The fluorimeter cell contained enzyme suspended at a concentration of 153 mg protein ml^{-1} in a solution containing FDP (triethylamine salt) 4 µM; Tris/Tris Cl (pH 7.7) 80 mM; EDTA (Tris salt) 1 mM; NaCl 133 µM. KCl was added from a motor-driven Agla syringe which delivered 5 µl of 150 mM KCl per minute. The syringe was stopped after 4 min, by which time the K^+ concentration was 1 mM. NaCl, to a final concentration of 17 mM, and ATP, to a final concentration of 27 µM, were added by hand. FTP fluorescence was excited at 310 nm and viewed at 380 nm as described in the legend to Fig. 1. An upward displacement of the trace represents a decrease in fluorescence and, because the rate of addition of KCl was very slow, the trace shows a succession of equilibrium states and gives no information about the rate of change of the enzyme (compare Fig. 4b).

the enzyme, though it could conceivably have been caused by a reduction in the fluorescence of bound FDP. The period of low fluorescence continued during hydrolysis of the FTP in the medium, and probably reflects the existence of a steady-state complex with a low affinity for nucleotide. The final rise in fluorescence may be attributed to binding of FDP from the medium as the concentration of FTP fell below its dissociation constant and the steady-state complex disappeared.

The presence of 1 mM K^+, added with the FTP, did not significantly alter the rate of fall of fluorescence (reflecting FDP release), though it did prolong the period of low fluorescence. The lack of effect of K^+ ions on the rate of fall of fluorescence is consistent with the Albers–Post sequence (see ref. 9), namely

$$E_1 + ATP \xrightleftharpoons[\quad]{Mg^{2+}, Na^+} E_1P.ADP \xrightleftharpoons[\quad]{\quad} E_1P + ADP$$

$$E_1P \xrightarrow{Mg^{2+}} E_2P \xrightarrow{K^+} P_i + E_2(K) \xrightarrow{ATP} E_1$$
where E_1 is a form of the enzyme, with a high affinity for ATP, which exists in predominantly Na media, E_1P is a phosphorylated form that can transfer its phosphoryl group to ADP, E_2P is a phosphorylated form that is hydrolysed slowly spontaneously, but rapidly in the presence of K^+ ions, and $E_2(K)$ is a form of the enzyme (containing occluded K^+) that is produced by K^+-catalysed hydrolysis of E_2P and is converted to E_1 by a reaction which is accelerated by the binding of ATP at a low-affinity site. The low level of fluorescence during steady-state hydrolysis, both in the presence and absence of K^+ ions, also supports this scheme, by providing evidence that the release of ADP precedes the step that is rate limiting—presumably E_2P hydrolysis if K^+ ions are absent and $E_2(K)$ breakdown if they are present. The prolongation of the period of low fluorescence in the presence of K^+ is simply the result of the reduction in the overall hydrolysis rate, which occurs because the breakdown of $E_2(K)$ at these very low nucleotide concentrations is slower than the spontaneous hydrolysis of E_2P.

A series of experiments like that of Fig. 3b, but with different FTP concentrations, showed that the fall in fluorescence was progressively accelerated as the FTP concentration was increased

in the range 2–20 µM, beyond which measurements were impracticable.

We have also used changes in the affinity for FTP and FDP to investigate the rates of interconversion of the dephospho-enzyme between a form (E_2) with a low affinity for nucleotide, which exists when K^+ is the predominant cation, and a form (E_1) with a high affinity for nucleotide, which exists when Na^+ is the predominant cation[5,10-12]. Figure 4a shows the slow increase in fluorescence that occurred when enzyme preincubated with 0.8 mM K^+ in the absence of Na^+ was mixed with an equal volume of buffer containing 4 µM FTP and 100 mM Na^+. No magnesium was present and the buffer concentrations were adjusted to minimise changes in ionic strength. Since the binding of FTP to enzyme preincubated with Na^+ is very rapid (~ 200 s^{-1} at 4 µM FTP), the rate-limiting step in the experiment of Fig. 4a must have been the conversion of the K form to the Na form, or some process associated with that conversion.

In a series of similar experiments, increasing the FTP concentration in the range 4 to 24 µM increased the rate constant for the increase in fluorescence from ~ 0.25 to ~ 0.85 s^{-1}. Again, this points to the existence of a low affinity FTP binding site, and it suggests that binding of FTP at the low affinity site accelerates the change in conformation.

Change in conformation in the reverse direction (Na form to K form) was monitored in experiments like that of Fig. 4b, in which enzyme that had been loaded with nucleotide in the presence of 300 µM Na^+ was suddenly exposed to 1 mM K^+.
Fig. 3 Stopped-flow records of fluorescence changes accompanying FTP hydrolysis by $(Na^+ + K^+)$-ATPase. Experiments were done at 20–21 °C using a stopped-flow fluorimeter based on that described in ref. 14 but modified for split-beam operation. Fluorescence was excited at 310 nm, and the emitted light was detected after passage through Wratten 18A and Schott K.V.370 filters, which excluded most of the light below 360 nm. Note that an upward displacement of the trace represents a decrease in fluorescence. Syringe I contained: enzyme 300 µg protein ml^{-1}; NaCl 76 mM; Tris/Tris Cl (pH 7.7) 19 mM; histidine 1.1 mM; EDTA 40 µM. Syringe II contained: FTP (triethylamine salt) 8 µM in Fig. 3a and 14 µM in Fig. 3b; MgCl$_2$ 2.4 mM; NaCl 76 mM; Tris/Tris Cl (pH 7.7) 19 mM. The two syringes delivered equal volumes to the mixing chamber. a, Changes in fluorescence for a period of 10 s after mixing, recorded with a Datalab transient recorder. The time constant of the apparatus was set at 100 ms. b, Outline of an oscilloscope trace from a separate experiment showing changes in fluorescence for the first 0.5 s after mixing. The time constant was set at 5 ms. The continuous line represents the equation

$$y/y_\infty = 1 - \exp(-13.6t)$$

and is intended merely to show that, discounting noise, the fall in fluorescence can be described by a single exponential.
Fig. 4 Use of formycin nucleotides and the stopped-flow fluorimeter to follow slow conformational changes of the dephosphoenzyme induced by altering the concentrations of K^+ and Na^+ ions. *a*, Syringe I contained: enzyme 540 µg protein ml^{-1}; KCl 0.84 mM; Tris/Tris Cl (*p*H 7.7) 87 mM; histidine 4 mM; EDTA (Tris salt) 1 mM. Syringe II contained: FTP (triethylamine salt) 8 µM; NaCl 100 mM; Tris/Tris Cl (*p*H 7.7) 4 mM. The addition of Na^+ and FTP to the K form of the enzyme produced a slow increase in fluorescence, presumably caused by binding of FTP to the Na form of the enzyme as soon as it appeared. The time constant of the amplifier was 50 ms. The figure reproduces the outline of the oscilloscope trace, and the smooth curve represents the equation

$$y = y_0 \exp(-0.26t)$$

b, Syringe I contained: enzyme 380 µg protein ml^{-1}; FDP (triethylamine salt) 4 µM; NaCl 330 µM; Tris/Tris Cl (*p*H 7.7) 100 mM; EDTA (Tris salt) 1 mM; histidine 4 mM. Syringe II contained: FDP (triethylamine salt) 4 µM; KCl 2 mM; Tris/Tris Cl (*p*H 7.7) 100 mM; EDTA (Tris salt) 1 mM. The addition of K^+ to enzyme-FDP caused a slow fall in fluorescence, presumably the result of dissociation of bound FDP that occurred as soon as the enzyme was converted to the K form. The time constant of the apparatus was 1 ms. The figure reproduces the outline of the oscilloscope trace, and the smooth curve represents the equation

$$y/y_\infty = 1 - \exp(-4.4t)$$

In these experiments, FDP was used rather than FTP to avoid any possibility of phosphorylation, and its concentration was kept constant by including it in both syringes. Mixing was followed by a slow fall in fluorescence with a rate constant of about $4.4\ s^{-1}$. Since, in a control experiment (not shown), displacement of FDP from the Na form of the enzyme by the addition of excess ATP led to a rapid fall in fluorescence ($k = 110\ s^{-1}$), the slow fall in Fig. 4*b* presumably reflects a slow change from Na form to K form.

Although in the conditions of Fig. 4*b*, a K^+ concentration of 1 mM should have been sufficient to displace FDP almost completely (see Fig. 2), the rate of change of fluorescence was increased about fivefold when the K^+ concentration was increased from 1 mM to 5 mM. The amplitude of the change was unaffected. The increase in rate implies that binding of K^+ ions to a low affinity site accelerates the change in conformation, and suggests that the sequence of events is

$$E_1 + K^+ \rightleftharpoons E_1K \longrightarrow E_2K$$

where E_1, the form of the enzyme with a high affinity for nucleotide, has a low affinity for K^+. It is economical to suppose that E_2K in this equation is identical with '$E_2(K)$', the form of the enzyme with occluded K^+, in the scheme described above. The remarkably slow rates seen in the experiments like that of Fig.

4*a* are certainly compatible with the longevity of the 'occluded form' postulated by Post, Hegyvary and Kume[13] at low nucleotide concentrations. If this identification is correct, it follows that the occluded form can be reached not only by K^+-induced hydrolysis of phosphoenzyme, but also by conversion from a form of the enzyme that binds K^+ at low affinity (?intracellular) sites.

General anaesthetics can selectively perturb lipid bilayer membranes

THE circumstantial evidence that anaesthetics act primarily by increasing the fluidity of membranes is quite strong. The gaseous, volatile, barbiturate, steroid and alcohol anaesthetics have all been shown to fluidise phosphatidylcholine–cholesterol lipid bilayers and the demonstration has also been made for some biological membranes[1–4]. Furthermore, a number of lipophilic substances, such as the higher alkanols, do not fluidise membranes and are not anaesthetics[3]. In some cases, a correlation between nerve-blocking potency and the action of anaesthetics in perturbing lipid bilayers has been observed[5]. Moreover, pressure counteracts the fluidising effects of anaesthetics just as it antagonises general anaesthesia *in vivo*[6–9]. The overall success of the fluidised lipid hypothesis tends to be its major drawback, for if anaesthetics fluidise membranes indiscriminantly then the hypothesis fails to provide a unique mechanism for their selective depression of neuronal function. We show here that lipid composition may modulate the ability of an anaesthetic to fluidise membranes more than has been generally supposed.

The effect of anaesthetics on membrane fluidity has been studied by intercalating fatty acids, or phosphatidylcholine (PC), labelled with a nitroxide reporter group into lipid bilayer membranes of various compositions. The anaesthetics studied showed wide variations in their ability to fluidise phospholipid bilayers. Results and experimental conditions are outlined in Table 1. All anaesthetics studied fluidised PC bilayers low in phosphatidic acid (PA) and high in cholesterol (Chol) (4%PA: 33%Chol) as evidenced by the consistent decrease in order parameter. At one extreme, halothane and urethane fluidised all the membranes studied, whereas at the other, pentobarbital and alphaxalone fluidised only those with 4%PA : 33%Chol.

Increasing cholesterol content conferred fluidising ability on all anaesthetics, but increasing the negatively charged PA tended to confer an ordering ability in some cases. A more detailed examination of the effects of lipid composition was made with pentobarbital and octanol (Table 2). The effect of pentobarbital switched from fluidising to ordering when, in the 4%PA : 33% Chol membranes, either the cholesterol content was lowered to 5–10% or PA was increased from 4 to 10%. Octanol always fluidised.

Our results in 4%PA : 33%Chol membranes are consistent with previous studies which have been carried out primarily in membranes of this cholesterol content, which is typical of nerve[2–4]. There are two isolated reports in the literature that halothane[11] and pentobarbital[12] order phospholipid membranes, as do local anaesthetics[12].

Spin-label[13] and deuterium magnetic resonance[14] studies suggest that the acyl groups of phospholipids are tilted near the head group region. General anaesthetics might reduce this tilt leading to a decrease in packing density as has been reported for tetracaine[13]. If so, the ordering effect should be weaker deeper in the bilayer and preliminary results with PC labelled with 8-doxylstearic acid at the β position are consistent with this explanation. In this context it is interesting to note that the three anaesthetics which increase anisotropy in the 4% PA bilayer all have structures which include rigid rings. A complete physical explanation of our results must await more detailed study, however.

The most important pharmacological aspect of this work concerns the specificity of action of anaesthetics. Although they are regarded conventionally as nonspecific drugs, many membrane processes are unaltered at anaesthetic doses. Thus the Na^+/K^+ ATPase of red blood cells[15] and synaptosomes[16] is unaffected at high, almost lytic, doses. This specificity might, *a priori*, reside in the primary perturbation of the lipid as well as in the secondary reaction of a given membrane protein to that lipid perturbation. Our work shows that the primary perturbation can no longer be thought of in terms of the lipid solubility of an anaesthetic alone; it is necessary to introduce the concept of fluidising efficacy, which we define as the rate of change of membrane fluidity with the concentration of anaesthetic in the membrane. Defined thus, fluidising efficacy

---

Table 1 The change in order parameter, ΔS, measured by 5-doxyl-stearic acid in lipid bilayer membranes exposed to anaesthetic agents

| Anaesthetic | Concentration | Bilayer composition, balance PC | | |
		4%PA	20%PA	4%PA:33% Chol
Halothane	11 mM	−0.03	−0.03	−0.06
Urethane	90 mM	−0.08	−0.03	−0.03
n-Octanol	46 mM	−0.02	−0.06	−0.08
Ketamine	25 mM	+0.03	0	−0.03
Alphaxalone	18 mM	+0.02	+0.03	−0.02
Pentobarbital	16 mM	+0.02	+0.02	−0.03

PC, Egg yolk phosphatidylcholine; PA, egg yolk phosphatidic acid; Chol, cholesterol; halothane is $CF_3CHClBr$; urethane is ethyl-carbamate; ketamine is 2-(methylamino)-2-(2-chlorophenyl) cyclo-hexanone and was a gift of Parke-Davis; alphaxalone is 3α-hydroxy-5α-pregnane-11,20-dione and was a gift of Glaxo. Lipids and spin labels in organic solvents were dried down together in pear-shaped flasks. Involatile anaesthetics were added in organic solvents before drying down; volatile agents were added later after the lipids had been dispersed in solution buffered at pH 7.0 by vortexing, and their concentration was checked by gas chromatography. Final lipid concentration was about 20–30 mg ml^{-1}, and the spin labels constituted about 1 mol % of the lipids. Anaesthetics were equilibrated with the bilayers up to 24 h before being sealed in 1-mm glass capillaries and equilibrated at 25 ± 0.5 °C in the cavity of either a Varian E-9 or E-109 electron spin resonance spectrometer operating at 9.5 GHz. Order parameters, ΔS, were calculated from spectra according to the method of Hubbell and McConnell[10]. A decrease in ΔS indicates a less anisotropic distribution of the label and a more fluid membrane. Changes in ΔS less than 0.01 were not considered significant. High doses of anaesthetics were used to obtain large changes in ΔS, which is a linear function of anaesthetic concentration within experimental error[2,3].

Table 2 The change in order parameter caused by anaesthetics in PC lipid bilayer membranes containing varying proportions of PA and Chol

| Anaesthetic | PA | Cholesterol | | | | |
		0	5%	10%	20%	33%
Pentobarbital	4%	+0.02	+0.02	0	−0.02	−0.03
16 mM	10%	—	+0.05	+0.04	+0.03	+0.05
	20%	+0.02	+0.09	+0.05	+0.02	+0.03
Octanol	4%	−0.02	—	—	—	−0.08
46 mM	10%	−0.05	−0.02	−0.03	−0.08	−0.04
	20%	−0.06	—	−0.03	−0.02	−0.03

---

need not be independent of anaesthetic concentration: thus Rosenberg reported unequivocal biphasic effects of halothane at physiological concentrations in palmitoyllauroyllecithin bilayers[11]. Most studies so far, however, have shown linear effects[2,3] or only weak nonlinear ones[4]. Three of the anaesthetics we examined could both order or fluidise bilayers, depending on their lipid composition, and thus indubitably exhibited both negative and positive fluidising efficacy; whereas for halothane, octanol and urethane, the fluidising efficacy was positive in all the membranes studied. For the latter anaesthetics we are unable to tell if the magnitude of the efficacy varies from membrane to membrane because the membrane solubilities are unknown. Our conclusions are thus based on the anaesthetics where a change in sign of the order parameter was observed.

To be consistent with the fluidised lipid hypothesis, anaesthetics should exhibit a positive fluidising efficacy at their site of action. In agreement with this, all six fluidised 4%PA: 33%Chol bilayers and pressure reversal of anaesthesia *in vivo* has been demonstrated for halothane[8,9], alphaxalone (as the clinical mixture althesin, which includes one third alphadolone acetate, a steroid with half the potency of alphaxalone)[9], pentobarbital[17], urethane[18] and ketamine (M. Wilson and K. W. M., unpublished). Long chain alcohols, which are not anaesthetics and do not fluidise membranes[3,19], might have lower efficacy than the short chain alcohols, or might simply have a lower membrane solubility. In the latter case, if the efficacy is about normal they might act additively with other anaesthetics as has been observed for some fluorinated hydrocarbons[20]. In all cases the magnitude of the fluidising efficacy can only be evaluated if the membrane partition coefficient is known, which is not often the case.

A corollary of the above argument is that only membrane regions where anaesthetics exhibit positive fluidising efficacy offer putative sites of action for anaesthetics. Thus, those anaesthetics, such as pentobarbital, which exhibit a positive fluidising efficacy in a restricted range of compositions might be useful for defining the nature of such sites. Our studies suggest they must have greater than 10% cholesterol and a charge density between 0.12 and 0.46 per phospholipid. This is consistent with the known compositions of neurones (30–50%Chol; 12–20% phospholipids bearing a single negative charge)[21], although our phospholipids are not typical of the variety found in biological membranes. Two factors could limit the usefulness of such an approach. First, the presence of protein in a lipid bilayer will probably exert an additional influence on the fluidising efficacy of anaesthetics–a single report that halothane orders rat brain synaptic membrane is cautionary[11]. Second, the lipids in biological membranes are heterogeneously distributed both across and in the plane of the membrane[22,23].

Large negative efficacies might also result in pharmacological effects[24]; indeed lipid ordering has been suggested as the cause of the hyperbaric convulsions exhibited by mammals at pressures in excess of 70 atm (ref. 25). We have shown that merely increasing the PA content from 4 to 10% in a 33% cholesterol bilayer changes the fluidising efficacy of pentobarbital from plus to minus. It remains to be seen how far the delicate balance

between anaesthetic and convulsant activities seen with many barbiturates can be explained in this manner.

Our work has been concerned exclusively with the primary anaesthetic-induced lipid perturbation. The sensitivity of membrane proteins to such perturbations might also vary.

Restriction map of 5S RNA genes of *Drosophila melanogaster*

ALTHOUGH certain segments of the primary sequence and secondary structure of 5S RNA seem to be strikingly similar in prokaryotes and eukaryotes[1], the genetic organisation of the 5S RNA genes themselves exhibits remarkable variability. In *E. coli*, several lines of evidence indicate that the multiple copies of the 5S, 16S and 23S rRNA genes are organised into transcription units containing one gene each plus a sequence coding either for $tRNA_1^{ILE}$ or $tRNA_2^{GLU}$ such that they are cotranscribed in the order 16S–4S–23S–5S RNA (refs 2 and 3). In eukaryotes, the 5S RNA genes may be clustered at a single site as in humans[4,5] or widely distributed on many chromosomes as in the case of *Xenopus laevis*, where the 5S genes are found on the telomeres of most, if not all, of the 18 chromosomes[6]. Among the eukaryotes, there is no example in which the 5S genes are tightly linked to the 18S and 28S rRNA genes. Although there has been a large number of papers reporting the cytogenetic localisation of the 5S RNA genes in various organisms, only in the case of *Xenopus laevis* are there data concerning the physical organisation of these genes[7]. Even in this instance, however, the structure is only known for a few 5S gene repeat lengths, and the long range order that might be imposed on an entire 5S DNA cluster within the chromosome remains obscure. Whereas long range order in certain satellite sequences has been described[8,9], similar higher order organisation has not as yet been revealed for transcribed redundant genes.

In the fruit fly, *Drosophila melanogaster*, there are approxi-

mately 160 5S RNA genes (5S DNA) per haploid genome[10,11]. Both genetic[11] and *in situ*[12] hybridisation data indicate that these genes are clustered in the euchromatic portion of chromosome 2 at the cytogenetic locus 56EF. Utilising a series of genetic deficiencies, we have shown that it is possible to split 160 tandemly repeated 5S RNA genes into two functional clusters, each containing about 80 genes[11]. The results of experiments with restriction endonucleases reported here have allowed us to construct a high resolution restriction map depicting the physical organisation of these genes. The physical structure of the 5S DNA is similar to their genetic organisation in that the 160 genes are organised as two distinct clusters of 80 genes each.

On treatment of wild-type *D. melanogaster* DNA with *Eco*RI restriction endonuclease, the fragments are separated by electrophoresis on 1% Agarose slab gels and transferred to a cellulose nitrate filter according to the method of Southern[13]. The filter-bound fragments were hybridised with ^{125}I-labelled 5S RNA and finally visualised by autoradiography. As seen in Fig. 1, *D. melanogaster* 5S RNA hybridises to a single size class of 23 kb (kilobases or kilobase pairs) in length. Two independently isolated mutants (*min*) deficient for 50% of the wild-
Fig. 1 Electrophoresis of *Eco*RI 5S DNA restriction fragments of wild-type and various *min* DNAs. *min* is a spontaneously derived mutant[11] and *min*[1] was obtained by triethylmalamine mutagenesis (Procunier and Tartof, unpublished). Each mutant contains half (0.003%) the number of wild-type 5S RNA genes. Approximately 10 µg of each DNA was digested with *Eco*RI in 0.05 ml of 50 mM Tris, *p*H 7.2, 50 mM NaCl, 10 mM $MgCl_2$ and 1 mM dithiothreitol at 37 °C for 2 h. A sufficient amount of enzyme was used to ensure complete digestion. The reaction was terminated by the addition of EDTA to 50 mM and NaCl to 0.20 M. The DNA was precipitated with 2 volumes of ethanol at −20 °C, collected by centrifugation and dissolved in E buffer (40 mM Tris, *p*H 7.2, 20 mM sodium acetate and 1 mM EDTA) containing 20% sucrose. Electrophoresis was carried out in 1% Agarose slab gels in E buffer for 4 h at 110 V. Following electrophoresis, the DNA fragments were transferred to a nitrocellulose filter according to the method of Southern[13] and then hybridised to ^{125}I-labelled 5S RNA (5 × 10⁷ c.p.m. µg⁻¹). The hybridisation reaction was carried out for 20 h at 60 °C by placing the filter in 10 ml of 2 × SSC (SSC is 0.15 M NaCl, 0.015 M sodium citrate, *p*H 7.0) with 0.20 µg of labelled 5S RNA and 400 times this amount of unlabelled 18S and 28S RNA. The filter was washed with 2 × SSC and treated with RNase (20 µg ml⁻¹) in 2 × SSC for 1 h at 37 °C. After another washing, the filter was dried at 60 °C and exposed to X-ray film (Ilford) for 13 d. *Eco*RI restriction fragments of phage λ DNA served as size standards (20.7, 6.8, 5.4 and 4.6 kb)[16]. From these, the size of the 5S DNA fragment was determined to be 23 kb.

Distance migrated (cm)
Fig. 2 Electrophoresis of *Hae*III 5S DNA restriction fragments. 400 μg of wild-type DNA were completely digested with purified *Hae*III at 37 °C in 6 mM Tris, *p*H 7.4, 6 mM NaCl, 6.6 mM MgCl₂ and 3 mM dithiothreitol. The enzyme was provided by Dr Jesse Summers of this Institute and purified according to Middleton *et al.*[17]. After digestion the reaction was terminated, DNA fragments precipitated and dissolved in E buffer according to the protocol of Fig. 1. Electrophoretic separation of the fragments was accomplished in 6% acrylamide —0.1% diacrylate gels (9.2 cm long, 0.45 cm diameter) in E buffer at 5 mA per gel for 1.5 h. The gel was frozen and sliced into 2-mm sections and each section dissolved in 50 μl of 1.5 N NaOH for 10 min at 70 °C. The mixture was neutralised with HCl and brought to a final concentration of 0.60 M NaCl, 0.20 M Tris and 0.02 M EDTA. The denatured DNA fragments were then covalently bound to phosphoimidazolol-cellulose filters according to Saxinger *et al.*[15]. The 5S ^{125}I-hybridisation reaction and subsequent RNase digestion was done as described previously (Fig. 1) and the filters dried and counted. Background values (identically treated filters but containing no DNA) were subtracted from the experimental values. *Hae*III restriction fragments of SV40 DNA provided the molecular weight standards in kilobases[18].

type number of 5S genes were similarly examined. The DNA from each of these also contains a 23-kb 5S DNA segment bounded by RI sites in spite of the fact that these mutants are deficient for half the wild-type number of these genes. This indicates there is more than one such 23-kb piece of 5S DNA per haploid genome.

To determine the number of *Eco*RI site bounded 5S DNA clusters, the precise size of the 5S repeating unit was obtained as follows. An *Hae*III cleavage point of 5S DNA can be predicted from the known *Drosophila* 5S RNA sequence[14]. The *Hae*III site

$$\begin{pmatrix} 5'\text{--GGCC--}3' \\ 3'\text{--CCGG--}5' \end{pmatrix}$$
is between base pairs 116 and 119 of the 120 base pair 5S gene. The Southern technique which uses nitrocellulose filters however, fails to detect DNA fragments smaller than 500 base pairs[13]. Since it was quite possible that the 5S gene repeat size was smaller, we looked for a way round this difficulty. This was achieved by first separating the products of *Hae*III digestion by electrophoresis on a 6% polyacrylamide gel, hydrolysing the gel slices and denaturing the DNA fragments with alkali and then covalently binding the DNA fragments to a carbonyldi-

imidazole-derivatised phosphocellulose filter according to the procedure of Saxinger *et al.*[15]. The DNA-bound filters were then hybridised with ^{125}I-labelled 5S RNA. The results from this experiment are shown in Fig. 2, where a single *Hae*III fragment 290 base pairs long is found to hybridise to 5S RNA.

The results of the RI and *Hae*III restriction experiments suggest the following structure for the 5S DNA of *D. melanogaster*. 160 5S RNA genes with a repeat length of 290 base pairs would require 46.4 kb. The RI cuts embrace a cluster of 5S RNA genes 23 kb long. Therefore, we conclude that there are two RI site-bounded clusters, each containing 80 tandemly arranged 5S RNA genes. Each of these genes in turn consists of a 120 base pair structural gene and a 170 base-pair spacer. It is also known that 5S RNA is 57% GC, yet the genes band in a CsCl gradient in a position indicating that the average repeating unit has a base composition similar to the bulk DNA which is 40% GC (Fig. 3). So, we reason that the spacer is approximately 72% AT. A summary of the physical and genetic maps of *Drosophila* 5S DNA is given in Fig. 4.

It is possible that there could be a second *Hae*III site in the spacer region which would produce a second fragment that we would not detect in our experiments because the first *Hae*III site occurs three bases from the end of the 5S structural gene leaving an insufficient 5S DNA tag to probe for. The size of the *Hae*III fragments (290 base pairs) multiplied by the number of genes (160) however, fits almost exactly the dimension required to accommodate two RI site-bounded clusters (46.5 kb com-

Fig. 3 Buoyant density of 5S DNA. 100 μg of wild-type DNA were mixed with CsCl such that the final density was 1.700 g cm⁻³ in a volume of 7 ml. The solution was centrifuged for 50 h at 50,000 r.p.m. in a Beckman type 65 rotor at 20 °C. Fractions were collected and the absorption at 260 Å and buoyant density (ρ) measured. Each fraction was then denatured with alkali, neutralised and finally immobilised on a nitrocellulose filter[19]. The filters were then hybridised for 20 h at 60 °C in 3 ml of 2 × SSC containing 10⁶ c.p.m. of ^{125}I-labelled 5S RNA (5 × 10⁷ c.p.m. μg⁻¹) and 100 μg unlabelled 18S and 28S RNA. At the end of the incubation time, the filters were washed with 2 × SCC, treated with RNase (20 μg ml⁻¹) for 60 min at 37 °C, washed again with 2 × SSC and then dried and counted. ○, [125]I-5S RNA; ●, A_{260}; ———, ρ.

Fraction no.

Translocation breakpoints
Fig. 4 A diagrammatic representation of the genetic and physical maps of the *Drosophila* 5S genes. From genetic evidence, it is known that the 5S DNA can be split into two functional clusters each of which contain approximately the same number of genes[11]. The designation and position of the translocation breakpoints which result in splitting the chromosome in the 5S DNA region are indicated. The physical map agrees with the genetic map in that there are two 5S DNA clusters of approximately equal size and bounded at the ends by *Eco*RI sites. The precise number of *Eco*RI sites and size of the DNA segment between the two 5S DNA clusters is unknown. The position of the *Hae*III site and the size and GC composition of structural gene and spacer are indicated.

pared with 46 kb), and this suggests to us that there is probably no other *Hae*III site in the spacer.

Two interesting aspects of the 5S DNA restrict n map deserve special comment. First, we do not know ei, er the quantity or the quality of the DNA segment inserted b 'ween the two 5S DNA clusters. The fact that one translocation breakpoint occurs between the two 5S DNA blocks (Fig. 4) suggests that the amount of DNA in this region must be appreciable. Second, the restriction map does not allow assignment of the relative order of the two tandemly arranged 5S DNA clusters with respect to each other. These clusters may be organised as direct serial repeats (a · b a · b) or as reverse repeats (a · b b · a). Unequal exchange between two direct serial repeats would be expected to produce genotypes containing variations in the number of RI site-bounded 5S DNA clusters. Indeed, one might expect the number of such clusters to increase enormously in the course of evolutionary time. Although our sample size is small, we have not observed such instability[11]. From such genetic considerations, we argue that a reverse repeat order of the two 5S DNA clusters would stabilise and preserve their structure in the chromosome. In addition, a palindrome arrangement would offer, on assuming the cruciform configuration, a means of maintaining homogeneity among both clusters through mismatch repair. We cannot but wonder if a similar arrangement might be imposed on other tandemly reiterated gene clusters.

Two proteins function in the regulation of photosynthetic CO_2 assimilation in chloroplasts

THERE is increasing evidence that products of the light reactions of photosynthesis govern the activity of enzymes involved in CO_2 assimilation by chloroplasts[1–15]. Of these products, reductants formed photochemically seem to be of particular importance. Such reductants include the reduced form of ferredoxin[2,6,16], a strongly electronegative chloroplast iron–sulphur protein ($E'_0 = -0.42$ V) that activates the two key chloroplast enzymes fructose 1,6-*bis*-phosphatase and sedoheptulose 1,7-*bis*-phosphatase. Activation of both of these enzymes requires in addition to reduced ferredoxin a 'protein factor' that is indigenous to chloroplasts. In efforts to elucidate the nature of the ferredoxin-linked enzyme activation, we have separated the protein factor into two components[16]: (1) a partly purified protein, provisionally named "assimilation regulatory protein a" (ARP_a) and (2) a highly purified chromophore-free protein called "assimilation regulatory protein b" (ARP_b). Only the latter was required for activation when reduced ferredoxin was replaced by the non-physiological sulphydryl reagent dithiothreitol[6,19].

The protein factor was resolved into the ARP_a and ARP_b components by following the reported purification procedure (fractionation by acid pH, acetone, ammonium sulphate, and Sephadex G-100 gel filtration)[6] that was modified to provide improved resolution in the gel filtration step.

Table 1 Requirement for ARP_a and ARP_b for activation of chloroplast fructose 1,6-*bis*-phosphatase by reduced ferredoxin

	nmol P_i released per min
Control	0
ARP_a	14
ARP_b	0
ARP_a plus ARP_b	73

The reaction was carried out in Warburg vessels containing (in the sidearm) 6 μmol of sodium fructose 1,6-*bis*-phosphate, and (in the main compartment) 135 μg of fructose 1,6-*bis*-phosphatase; spinach chloroplast fragments, P_1S_1, equivalent to 0.1 mg chlorophyll[6]; 0.12 mg of spinach ferredoxin, and the following (μmol): Tris-HCl buffer, pH 8.0, 100; neutralised reduced glutathione, 5; sodium ascorbate, 10; 2,6-dichlorophenolindophenol, 0.1; $MgCl_2$, 1.85 μg of ARP_a and 108 μg of ARP_b, were added as indicated. Vessels were equilibrated with nitrogen for 6 min and were then incubated for 5 min in the light. The reaction was started by adding fructose 1,6-*bis*-phosphate from the sidearm and was continued for 30 min under illumination. Light intensity, was 20,000 lx and temperature was 20 °C. The reaction was stopped by adding 0.5 ml of 10% trichloroacetic acid and (after removing the precipitate by centrifugation) P_i was estimated by a modified Fiske–SubbaRow procedure[6].

Although ARP_a and ARP_b were not completely separated, even after improvement in the gel filtration step, fractions of the two components were sufficiently resolved to establish their separate identities. ARP_b was then further purified by DEAE–cellulose chromatography and a second Sephadex G-100 gel filtration step. Details of the additional purification procedure will be published elsewhere.

Ultracentrifugation of purified ARP_b (single absorption maximum at 280 nm) showed one component with an approximate molecular weight of 20,000 but polyacrylamide gel electrophoresis yielded two components, both of which showed ARP_b activity. It seems therefore that ARP_b can exist in more than one form.

Table 1 demonstrates that both ARP_a and ARP_b were required for activation of fructose 1,6-*bis*-phosphatase by reduced ferredoxin. By contrast (Table 2), only ARP_b was required for activation of the enzyme when reduced ferredoxin was replaced by dithiothreitol. Similarly, the dithiothreitol-induced activation of the sedoheptulose 1,7-*bis*-phosphatase activity that occurs when the chloroplast fructose 1,6-*bis*-phosphatase is converted from its dimer to its monomer form when the pH is increased from 5.5 to 8.5 (ref. 17) required only ARP_b.

In addition to its activation of the fructose 1,6-*bis*-phosphatase and sedoheptulose 1,7-*bis*-phosphatase enzymes of chloroplasts, ARP_b was found to activate the regulatory form of NADP–glyceraldehyde phosphate dehydrogenase[14,18] in the presence of dithiothreitol (Table 3). Neither the NAD-linked activity of the regulatory form of the enzyme nor the NAD(P)-linked activity of its non-regulatory counterparts was affected by ARP_b. In the presence of dithiothreitol, ARP_b also activated one of the two forms of phosphoribulokinase that we have found in chloroplasts (Table 3). In neither case could other sulphydryl reagents replace dithiothreitol.

In summary, the evidence indicates that ARP_a and ARP_b, two newly discovered chloroplast proteins, link the strong reducing power of photochemically reduced ferredoxin to the regulation of certain enzymes of photosynthetic CO_2 assimilation. We believe that the ferredoxin-linked system constitutes a specific mechanism of enzyme regulation that operates in addition to the other light-actuated systems of chloroplasts. Of the latter group, those mechanisms involving enzyme effectors (such as reduced NADP) would govern

Table 3 Effect of preincubation with ARP_b and dithiothreitol on chloroplast NADP–glyceraldehyde phosphate dehydrogenase and phosphoribulokinase

	$\Delta A_{340\ nm}$ per min Preincubation with	
	dithiothreitol	ARP_b plus dithiothreitol
NADP–glyceraldehyde phosphate dehydrogenase	0.30	1.14
Phosphoribulokinase	0.04	0.37

To assay NADP–glyceraldehyde phosphate dehydrogenase, 90 µg of the regulatory form of the enzyme[14] was preincubated for 3 min in a solution containing (in a volume of 0.1 ml) 10 µmol of Tricine–NaOH buffer, pH 8.4; 1 µmol of dithiothreitol, and, as indicated, 9 µg of ARP_b. After preincubation, the mixture was injected into the assay mixture that contained, in a volume of 0.9 ml, 3 µg of 3-phosphoglycerate phosphokinase and the following (µmol): Tricine–NaOH buffer, pH 8.4, 40; dithiothreitol, 1.5, $MgCl_2$, 10; ATP, 5; 3-phosphoglycerate, 5; NADPH, 0.12. Enzyme activity was measured by following the change in absorbance at 340 nm. The temperature was 22 °C. To assay phosphoribulokinase[24] (the form present in the purified fraction containing the regulatory form of NADP–glyceraldehyde phosphate dehydrogenase[14]), 90 µg of the enzyme was preincubated for 3 min in a solution containing (in a volume of 0.1 ml) 10 µmol of Tris-HCl buffer, pH 7.5; 1 µmol of dithiothreitol, and, as indicated, 9 µg of ARP_b. After preincubation, the mixture was injected into the assay solution that contained, in a volume of 0.9 ml, 10 µg of phosphoribuloisomerase; 60 µg of lactate dehydrogenase; 30 µg of pyruvate kinase, and the following (µmol): Tris-HCl buffer, pH 7.5, 100; reduced glutathione, 10; $MgCl_2$, 10; ribose-5-phosphate, 2; phosphoenolpyruvate, 0.5; ATP, 0.5; NADH, 0.12. Enzyme activity was measured by following the change in absorbance at 340 nm. The temperature was 22 °C.

the activity of selected regulatory enzymes, whereas other mechanisms (for example, those involving light-induced increases in the pH (refs 19, 20) or Mg^{2+} concentration[21,23] of the stroma or soluble phase of chloroplasts) would provide the environment necessary for the optimal activity of enzymes of the reductive pentose phosphate cycle.

Table 2 Activation of the fructose 1,6-*bis*-phosphatase and sedoheptulose 1,7-*bis*-phosphatase activities of chloroplast fructose 1,6-*bis*-phosphatase by ARP_b and dithiothreitol

Treatment	nmol of P_i released per min Fructose 1,6-*bis*-phosphatase	Sedoheptulose 1,7-*bis*-phosphatase
Complete	168	131
Minus $MgCl_2$	7	1
Minus ARP_b	14	58
Minus fructose 1,6-*bis*-phosphatase	6	4
Minus dithiothreitol	11	4
Minus dithiothreitol, plus reduced glutathione	10	4
Minus dithiothreitol, plus β-mercaptoethanol	11	5

To assay fructose 1,6-*bis*-phosphatase activity, the complete system contained 8 µg of the dimer form of fructose 1,6-*bis*-phosphatase[17], 9 µg of ARP_b, and the following (µmol): Tris-HCl buffer, pH 8.0, 100; $MgCl_2$, 1; dithiothreitol, 5; and fructose 1,6-*bis*-phosphate, 6. The final volume was 1.0 ml. To assay sedoheptulose 1,7-*bis*-phosphatase, the complete system contained 16 µg of the monomer form of fructose 1,6-*bis*-phosphatase (obtained from the enzyme dimer by increasing the pH from 5.5 to 8.5 (ref. 17); 9 µg of ARP_b, and the following (µmol): Tris-HCl buffer, pH 8.0, 100; $MgCl_2$, 10; dithiothreitol, 5; sedoheptulose 1,7-*bis*-phosphate, 1.5. The final volume was 1.0 ml. In each case, the reaction (at 25 °C) was started by the addition of enzyme and stopped by the addition of 4 ml of the mixture used for P_i analysis (see Table 1).

matters arising

Biotic extinctions by solar flares

REID *et al.*[1] have suggested a mechanism by which solar protons might catastrophically deplete atmospheric ozone during a reversal of the Earth's geomagnetic field, when its shielding effect is weakened. Organisms would thereby be exposed to a harsher ultraviolet environment, producing extinctions, such as those Hays[2] observed, closely correlated with geomagnetic reversals in deep-sea sediment cores. They further suggest that mass extinctions, such as those which took place at the close of the Cretaceous, may have thus occurred. Reid *et al.* assume that during a reversal the geomagnetic field effectively disappears for $\sim 1,000$ yr. They also assume that solar flares sufficiently intense to cause extinctions occur at intervals of $\sim 1,000$ yr or more. We propose to examine the validity of these assumptions by comparing them with geomagnetic reversals identified by Tarling and Mitchell[3] for the past 75 Myr, and small scale (radiolarian) and large scale (dinosaurian) extinctions.

Hays[2] found four radiolarian cases of extinction (involving 6 species) during the past 2.5 Myr, in which time 10 geomagnetic reversals occurred[3]. According to the model proposed by Reid *et al.*, the expected number of extinction events (E) is related to the probability of occurrence of a strong solar flare during any year (P_s) and the number of successive years during which the magnetic field is effectively absent (T) as

$$E = RTP_s \qquad (1)$$

where R is the number of reversals during the period considered. Solving for P_s, and substituting the values cited above:

$$P_s = E/RT = 4 \times 10^{-4} \text{ yr}^{-1} \qquad (2)$$

The value for P_s is lower than assumed by Reid *et al.* Given their estimate of $P_s = 10^{-3} \text{ yr}^{-1}$, to satisfy equation (1), the magnetic field would have to disappear for 400 yr during a reversal, an interval shorter than the generally accepted value[4]. A reduction in P_s would not, in our view, impair the utility of the model proposed by Reid *et al.* in producing periods of small scale extinction.

It is, however, evident that the terminal Cretaceous (dinosaurian) extinctions affected a much broader range of organisms[1,5] than the radiolarian ones described by Hays. The extinction of the dinosaurs occurred within a short but undefined interval ~ 18 Myr after the end of a lengthy period of normal polarity[6,7]. During these 18 Myr, eleven reversals took place[6], but the diversity of terrestrial and marine reptiles remained constant up to the end of the Cretaceous[8].

A solar flare powerful enough to produce such extinctions would, therefore, have been much more powerful than any directly considered by Reid *et al.* Because no extinction as severe as those in which the dinosaurs were eliminated have subsequently taken place (or $E = 1$), and at least 197 reversals have since occurred ($R = 197$; set $T = 10^3$ yr), then the frequency of a hypothetical giant flare according to equation (2) is

$$P_s = (1.97 \times 10^5 \text{ yr})^{-1}$$

or ~ 1 per 200,000 yr. Solar proton events have been studied only during the past 15–20 yr (ref. 1), and there is little hard evidence for the existence of giant flares, although instabilities in solar activity are now receiving more attention than formerly[9]. We therefore concur that the supernova model, as proposed by Terry and Tucker[10] and Ruderman[11] remains worthy of consideration. Although the coincidence of a reversal and the terminal Cretaceous extinctions would invalidate neither model, Keating[12] notes that this coincidence has not been demonstrated.

CRUTZEN AND REID REPLY—We certainly agree with the interesting remarks of Béland and Russell[1]. Our model was primarily intended to provide a tentative explanation for the apparent mysterious association between geomagnetic polarity reversals and small scale extinctions, as documented by Hays[2]. The relationship between polarity reversals and mass extinctions, such as that at the close of the Cretaceous, is not well established, and our mechanism is only a possible candidate.

In terms of ionising radiation, the solar flares of August 1972 dissipated $\sim 6 \times 10^5 \text{ erg cm}^{-2}$ in the polar stratosphere. A similar flux of energy over the entire projected area of the Earth would be caused by the γ-ray 'pulse' ($\sim 10^{49}$ erg (ref. 3)) from a supernova 1,000 light yr away, while a supernova 30 light yr away would create a flux 1,000 times larger. It is not likely that the Sun could produce such a colossal flare, but several supernovae may have occurred within a distance of 30 light yr during the lifetime of the Solar System[4].

Although the shielding of ultraviolet light by NO_2 must be considered, any ozone depletion caused by such supernovae would seriously affect the biosphere[5]. However, other consequences of the vast amounts of nitrogen fixed in the atmosphere are worth considering. Assuming maximum efficiency of NO production, the supernova would fix $\sim 1,500$ Mt of nitrogen, which is almost 10 times the presently estimated annual global nitrogen fixation rate[6]. This could perturb ecological systems. Furthermore, the column density of NO_x could initially reach unhealthy concentrations of 10^{19}–10^{20} molecules per cm^2 and although detailed calculations are necessary to confirm the idea, it may seem that there could be substantial production of NO_2 and even O_3 by the reaction $2NO + O_2 \rightarrow 2NO_2$. Given absorption cross sections of $NO_2 > 10^{-19} \text{ cm}^2$ at wave lengths $\lesssim 650$ nm, severe perturbations in photosynthesis rates and in the radiation balance of the Earth may result.

Glaciations and dense interstellar clouds

As a possible cause of an ice age on Earth, I have suggested the passage of the Solar System through a region of compression of interstellar matter (ISM) bordering a spiral arm of the Galaxy[1]. Dennison and Mansfield criticise the model because it leads them to expect to find a dense cloud of ISM still very close to us; no such cloud is seen[2]. Their criticism, however, ignores the structure of the Galaxy that provides the basis for my suggestion, and the justification for reviving the idea of a possible relation between ISM and ice ages.

The compression region is a shock region, that is, a 'traffic jam', in the ISM. According to the model, the most recent glaciation was associated with the Sun having been immersed in a cloud of ISM while it traversed such a region. On my interpretation, the Sun emerged from the region after that. Dennison and Mansfield adopt ~ 20 km s^{-1} for the relative speed of the Sun and cloud, and $\sim 10^4$ yr ago for the time of emergence.

Dennison and Mansfield take no account of the fact that the Sun and cloud were travelling through the region with mean speed ~ 250 km s^{-1} in their orbital motion round the Galaxy. So the place where the Sun emerged from the cloud is more than 10 times further off than in the reckoning of Dennison and Mansfield.

The material of the cloud concerned did indeed emerge from the compression region about the same time, but there are three essential points to recognise: (1) The region forms an oblique shock and, viewed as such, it produces a discontinuity in direction of flow of the ISM passing through it, but not of the stars. After emerging from the region, the cloud material and the Sun have relative motion very different from what they had in it. The traffic-jam is like congestion on an escalator—after people get off an escalator they disperse with relative speeds comparable to the speed of the escalator, not to the relative speed they had while on the escalator. (2) When the material emerges it is no longer compressed, since by definition the compression region is the region where it is compressed. Compression regions themselves are common places of observation, but how the compressed material evaporates out of them is not understood in detail. (3) There is no reason to suppose that clouds retain their individuality as the ISM evaporates from a compression region.

The answer to Dennison and Mansfield is that the dense cloud they expect is not where they infer, it is not dense, and it is not a cloud.

For reasons I have stated briefly elsewhere[1,3], the end of the most recent glaciation could have been the very end of a period of glacial activity that did not even start until after the Sun had emerged from the cloud, and its luminosity had fallen back to normal after an interval of enhancement. Thus the time, $\sim 10^4$ yr, is almost certainly an underestimate. In their closing paragraph Dennison and Mansfield go some way towards admitting this further general consideration and its implications. I should take issue with them over several other particular matters were this necessary. It seems, to me, however, that their objections vanish in the light of the foregoing general considerations, and that their discussion actually helps to show that there need be no embarrassing side effects in the model.

I was aware of the problem of a nearby cloud raised by Hoyle and Lyttleton in a paper[4] I quoted in ref. 1, and recalled by Dennison and Mansfield, but ideas on the Galaxy and the kinematics of ISM have changed since 1939.

DENNISON AND MANSFIELD REPLY—On encountering a spiral density wave, interstellar matter (ISM) suffers rapid and substantial changes in its flow field and density. Behind the shock, the gas gradually recovers over some millions of years[1]. The actual shock region is extremely narrow, and thus the transit time of the stars and gas through it is negligible in comparison to a million years, the approximate duration of the last general ice age. Behind the shock, the ISM, or any cloud, could not undergo significant changes in velocity, density, or identity caused by spiral density wave in the $\sim 10^4$ yr since the last glaciation, or even in the $\sim 7 \times 10^4$ yr since the beginning of the last glaciation. To accomplish the rapid changes now proposed by McCrea[2], an unjustified assumption of a second abrupt change in the flow field of the ISM behind the initial shock would have to be made. The compression region fades gradually—it does not end abruptly like people leaving an escalator.

Before entering the compression region, the stars and ISM have a small velocity differential of ~ 10 km s^{-1}, because they follow similar orbits. In entering the compression region, the ISM is severely perturbed, while the stars are largely unaffected. This produces velocity differentials between the stars and gas that are an order of magnitude larger than the 5–25 km s^{-1} that McCrea uses. His low velocity differentials are appropriate for regions outside the compression zone. Since the 'traffic jam' applies to the ISM only, it is in the compression zone that there are large velocity differentials, and because the accretion rate in the model depends linearly on the cloud density and inversely as the cube of the velocity differential, the same fractional increase in solar luminosity would now require the frequent encountering of clouds with embarrassingly high densities, from $\sim 10^8$ to $\sim 10^{10}$ hydrogen molecules cm^{-3}.

Even if we accept the unorthodox picture that McCrea now uses, an excessive amount of energy is needed to dissipate these dense clouds on time scales of $\sim 10^4$ yr. A typical cloud required by the original model has $\sim 10^6$ hydrogen molecules cm^{-3} and a diameter of ~ 1 pc. Such dense clouds cool rapidly and cannot store compressional energy. It is easy to show that over a time of $\sim 10^4$ yr a power of $\sim 5 \times 10^4 L_\odot$ is required to overcome the gravitational binding of the cloud. McCrea's present model would require the dissipation of many such clouds throughout the disk of the Galaxy. This requires that on the average a power $\gtrsim$ total luminosity of the Galaxy must be constantly expended in dissipating dense clouds.

reviews

Provocative and rewarding genetics

William J. Schull

Genetics, Evolution and Man. By W. F. Bodmer and L. L. Cavalli-Sforza. Pp. xv+782. (Freeman: San Francisco, 1976.) $13.95.

FIVE years ago, these authors gave us *The Genetics of Human Populations* (1971), a book addressed more to the specialist or advanced student than the neophyte. *Genetics, Evolution and Man* projects the notions set forth in this earlier effort on to a wider, less specialised readership. Their newer book expands the admirable features of its predecessor—excellent illustrations, conceptually and graphically; succinct abstracts at the beginning of each chapter, providing a sense of direction for the reader; the intercalation of frequent one-or two-line statements which capture the essence of the paragraphs which follow; problems which test and supplement one's understanding of each chapter; and a lucid, readily readable literary style. More important, perhaps, is its currency and the overall objectivity which Bodmer and Cavalli-Sforza bring to the task which they set for themselves. This does not imply that every human biologist will subscribe fully to their arguments on controversial issues—for example, the roles of heredity and environment in the observed differences among the races in tests of intelligence. Even where honest differences of opinion exist, however, it should be clear to all save the most committed that they make a serious appeal to reason rather than exhibit a preconception or prejudice.

This is unquestionably an important book, and everyone familiar with the subject matter must appreciate the wealth of information to which the un-initiated reader is exposed. It is provocative, but not provoking; it rewards without remonstrating. Each reader, indeed each reviewer, will undoubtedly be attracted to a different chapter. One of my favourites is the "Evolutionary Development of Modern Man". It attempts a synthesis of man's biological and social evolution as a human population geneticist might see it. The observations on which this synthesis is based are, of course, sensitive to substantial differences of interpretation both as to time and significance. Illustrative of such differences are the re-

ferences to the Jomon culture of Japan. Development of pottery by this culture is cited to be 9,000 yr ago, but *Japan; Its Land, People and Culture* (UNESCO 1958) suggests this event actually occurred about 14,000 yr ago; whereas the 'earliest Jomon' is given by Komatsu (*The Japanese People*, 1962) as about 6,400 yr ago. Apparently, Bodmer and Cavalli base their estimate on the carbon dating, carried out at the University of Michigan some years ago, of charred wood recovered from the Natsushima shell-mound in Kanagawa Prefecture. This specific example is not particularly important and quite possibly the figure given by Bodmer and Cavalli may be correct, but some of the 'facts' of their general argument will undoubtedly prove to be in error. This, however, is a much lesser moment than the synthesis and its respect for the divergent data sets which must, in some manner, be integrated. Their view does not disregard man's cultural evolution nor does it consciously serve the biological sciences. They acknowledge man's biological and cultural heritage; and seek

a quantitative appraisal of the contributions of these elements to his present diversity, not a capitulation on the part of one or the other disciplinary views.

If fault one must find, then this book is overly long. This stems, I believe, first, from a misdirected effort to make the book self-contained—that is, to provide the reader with every detail necessary to understand some of the subsequent arguments; and second, a failure to realise the frequency with which most students are exposed to the structure of DNA, the mechanics of mitosis, and elementary notions of statistics. This is not to suggest that reinforcement is not needed for some —possibly a large number—but a general application of repetition can just as readily lead to boredom as understanding. This is a small caveat, and doesn't seriously compromise the book's general excellence. ☐

William Schull is Director of the Center for Demographic and Population Genetics at the University of Texas Health Science Center, Houston, Texas.

Introduction to methods of geophysics

Geophysical Methods in Geology. (Methods in Geochemistry and Geophysics, Vol. 12.) By P. V. Sharma. Pp. xv+428. (Elsevier Scientific: Amsterdam, Oxford and New York, 1976.) Dfl. 65; $26.25.

HERE is a book that attempts to cover the techniques used in the whole field of geophysical research on the crust and lithosphere, industrial and academic; that is, a book that combines the contents of books such as Parasnis (1972), Bott (1971), York and Farquhar (1972) and Cox (ed. 1973). There are chapters on seismic methods (with sections on fundamentals of seismic wave propagation, seismic seismicity and seismotectonics, seismic prospecting, use of surface waves in crustal studies), gravity methods, magnetic methods (from Wenner spreads to magnetotellurics), radiometric methods (dating and prospecting), geothermal methods

and, finally, geophysics applied to global tectonics. The book is polymath, up-to-date and non-mathematical; SI units are used and a point in its favour is that most subsections end with a reference to a recent review article. It is a long book but not a verbose one.

Dr Sharma writes that the book developed from a course organised at the University of Copenhagen. "The course was aimed at providing a concise but fairly comprehensive introduction to the methods of geophysics within which the undergraduate students of geology and geophysics could locate their specific interests for further specialisation." He does not tell us in which year of their undergraduate career these students received this course. No man could have a lively research acquaintance with one half of the subjects touched on here so that the course (and the book) must have represented a con-

siderable piece of scholarship; but I feel that, in consequence, the book is at once too comprehensive and too facile to arouse the lively interests of an undergraduate reader. I shall continue to encourage the second- and third-year undergraduates whom I encounter to read Parasnis, Bott and Cox.   **D. Matthews**

Dr Matthews is a reader in the Department of Geodesy and Geophysics at the University of Cambridge, UK.

Planetary interaction

Interplanetary Encounters: Close-Range Gravitational Interactions. (Developments in Solar System and Space Science, 2.). By Ernst J. Öpik. Pp. vii + 155. (Elsevier Scientific: Amsterdam, Oxford and New York, 1976.) $26.95; Dfl.67.

THIS is an excellent book, a book that any scientist will read with awe, realising that very few of their number can, in the fullness of years, produce such a resumé of original work.

Ernst Öpik has been an astronomer of international renown since the early 1920s, his main interest centring on the Solar System. In this book he deals with the encounters between planets and between planets and stray bodies such as meteorites, asteroids and comets. These gravitational interactions sometimes lead to collisions— more often to changes in the orbital parameters of the two bodies and the possible ejection of one from the Solar System. Öpik has advanced from the restricted three-body problem to formulate a probability method reliant on two-body interactions over specific spheres of influence. This leads to a statistical celestial mechanics which culminates in the prediction of the cratering densities of Mars and Moon, dynamical lifetimes of cometary debri and other stray bodies, solutions to the Neptune–Pluto problem, stability of the Trojan asteroids, and many more phenomena.

The book summarises and refines a series of some 29 research papers written by the author between 1951 and 1972; it is beautifully produced, very clearly indexed and is essential reading for all Solar System astrophysicists.   **David W. Hughes**

David Hughes is a lecturer in the Department of Physics at the University of Sheffield, UK.

Quite recently, biological motivation has contributed new ideas to computer science and mathematics, while these disciplines have provided useful insights to biological development. North-Holland takes pleasure in detailing below three authoritative publications covering this new field.

Developmental Systems and Languages

by GABOR T. HERMAN *and* GRZEGORZ ROZENBERG.

With an introductory chapter by ARISTID LINDENMAYER, *Subfaculty of Biology, University of Utrecht.*

1975 xvi + 366 pages 10 tables 59 illus. over 200 lit. refs.
Price: US $28.95 / Dfl. 75.00; ISBN 0-7204-2806-8

The application of the rigorous techniques of formal language theory to biologically motivated concepts gave rise to the theory of developmental systems and languages. This area has been actively investigated over the last few years, yielding many results of fundamental interest to both the formal language theorist, the biologist and the computer scientist.

Self-contained, this book provides an exhaustive and up-date survey of the field. After an introduction in which the biological motivation of the study is described, the book is divided into three main sections. Part I gives a formal presentation of the theory of *developmental languages* while Part II treats the theory of *developmental sequences*. Part III offers a less formal discussion of topics whose biological motivation is more apparent.

Automata, Languages, Development

At the crossroads of biology, mathematics and computer science

edited by ARISTID LINDENMAYER *and* GRZEGORZ ROZENBERG.

1976 viii + 529 pages Price: US $46.00 / Dfl. 120.00; ISBN 0-7204-0474-6

A truly interdisciplinary exposition, this book represents the work of many distinguished scientists, brought together by their common interest in understanding the *algorithmic nature of developmental processes.* It includes both survey articles and specialized research papers covering recent trends in each of the following interrelated areas:

- mathematical and computer models for growth and development of multi-cellular organisms,
- the theory of L systems, and its relation to the formalization of multi-cellular development and regeneration,
- the theory of cellular automata and tessellation structures, and its relation to the concept of self-reproduction,
- the theory and applications of graph generating and related systems.

This book is based largely on the extension of material presented at a conference held at Noordwijkerhout, Holland, in April, 1975. Biologists, mathematicians and computer scientists will find this work a thoroughly representative and balanced review of the latest developments in an increasingly important interdisciplinary area.

Analysis and Control of Immobilized Enzyme Systems

edited by DANIEL THOMAS *and* JEAN-PIERRE KERNEVEZ.

1976 vii + 306 pages 22 tables 119 illus.
Price: US $27.50 / Dfl. 70.00; ISBN 0-7204-0361-8

This volume contains the proceedings of an international symposium held in Paris, May 1975 which was devoted to analysis and regulation of immobilized enzyme systems. The aim of the symposium was to bring together researchers from different fields, viz., biochemistry, applied mathematics and computer sciences, with the main emphasis laid on experimental and theoretical analysis of immobilized enzyme systems as biological models. The indentification of kinetic parameters as well as the control of enzyme systems ruled by partial differential equations, are presented.

obituary

Walter Schottky, author of many significant contributions to the fields of electron and solid-state physics, died on March 4, 1976 at the age of 89. Born in Zürich, he studied under Max Planck at the University of Berlin, and subsequently held university appointments in Wurzburg and Rostock. His first research interest lay in the field of electron physics, and what is now universally called the 'Schottky effect' (the increase in the thermionic emission of electrons from a solid resulting from an external electric field) dates from as far back as 1914.

Possibly as a result of the First World War, Schottky next turned his attention to the radio and in 1915 invented the screened-grid vacuum tube. He is also credited with the invention of the superheterodyne receiver. He studied the 'shot noise' which arises from the discrete nature of the charge carriers in a current of electrons, and in 1918 derived the well-known relationship between the magnitude of the noise and the strength of the current. For these three contributions he was awarded the Hughes Medal of the Royal Society in 1936.

After the war, Schottky's interests turned to thermodynamics and statistical mechanics. One result of this was his prediction of the 'Schottky specific heat anomaly'—the specific heat of a system possessing two closely spaced, discrete energy levels shows a maximum at a temperature comparable with the separation between the levels divided by Boltzmann's constant. His analysis successfully explains specific heat behaviour which has been observed on numerous occasions by low-temperature physicists. His postulation of the existence of 'Schottky defects' in crystals (missing atoms without compensating atoms in interstitial positions) also dates from this period.

In 1927, Schottky became closely associated with the firm of Siemens, thereby continuing a well-established German tradition. From that time onwards he turned his attention to semiconductors, and in particular to the properties of metal–semiconductor contacts, and it is for this work that he is probably most widely known today. It had been known since the early work of Braun in 1874 that metal points in contact with certain solids, such as lead sulphide, show rectifying properties, and although these point-contact rectifiers were not understood, they nevertheless played a most important role as detectors in the early days of radio. In 1931 Schottky and his co-workers showed that in copper oxide rectifiers nearly all the potential drop occurred near the metal contact, thereby implying the existence of some sort of potential barrier. By this time quantum mechanics was firmly established, and Wilson and others tried to explain the rectifying action in terms of the quantum-mechanical tunnelling of electrons through the barrier, but it was soon recognised that this mechanism predicted the wrong direction of easy current flow. Schottky, and independently Mott, suggested that the rectifying action resulted from the thermal excitation of electrons over the barrier, and showed that this model predicted the correct direction of rectification. Schottky supposed that the barrier region contained a space charge caused by a uniform density of charged impurities, so that the electric field increased as the metal was approached, whereas Mott assumed that the conditions of fabrication were such that the barrier region was devoid of impurities, so that the electric field was constant. We now know that Schottky's assumption is the more realistic one in practice, and in consequence the term 'Schottky barrier' is used almost universally to describe a metal-semiconductor contact. Schottky also derived an expression for the capacitance of the contact in terms of the density of charged impurities, and showed how measurements of the capacitance could be used to infer the impurity concentration. This technique is used very extensively throughout the semiconductor industry today.

Schottky was a very versatile physicist who combined a wide theoretical knowledge with a deep physical insight and the ability to look at problems from a practical point of view. He was always ready to apply his science to engineering problems, and it is perhaps appropriate that the term 'Schottky diode' is now firmly established in the vocabulary of electronic engineers who probably know little of his contributions to basic physics.

E. H. Rhoderick

The sudden death of **Professor Richard Foster Flint** of Yale University on June 6, 1976, deprived the world of one of the most eminent of its Quaternary geologists of any generation. Born in Chicago, Illinois, on March 1, 1902, the son of Professors Nott William and Edith Burnham (Foster) Flint of the University of Chicago, he obtained his B.S. in 1922 and his doctorate, *summa cum laude*, from that University in 1925. He joined the Yale University faculty as Instructor the same year and taught at Yale for the next 45 years. He retired in 1970 as Henry Barnard Davis Professor of Geology, the occasion being commemorated by a symposium in his honour and a resulting Festschrift (*The Late Cenozoic Ice Ages*) to which some of the world's leading researchers contributed.

Professor Flint's publications number over 150 research papers and a series of monographs including *Glacial Geology and the Pleistocene Epoch* (1947), *Glacial and Pleistocene Geology* (1957), and *Quaternary and Glacial Geology* (1971). The last stands as the most up-to-date, comprehensive, and masterful overview of the subject in any language. He was also the co-author of a number of editions of such famous Yale texts as *Physical Geology* and *Introduction to Physical Geology*. Especially influential was his stimulating teaching that opened the exciting vistas he saw to generations of Yale graduate students and undergraduates— thousands of the latter benefited from his introductory course on the earth sciences. He also enhanced Yale's reputation by serving as associate-editor, co-editor, or member of the editorial board of a number of scientific journals, including *American Journal of Science, Quaternaria, Quaternary Research, Radiocarbon* and *Zeitschrift für Geomorphologie*. In addition he was Chairman of the National Research Council committees that compiled the Glacial Map of North America and the Glacial Map of the United States.

Professor Flint once said that he did not expect great fame as a scientist, since he desired a life whose breadth would necessarily detract from single-minded scholarship. Yet he not only achieved the full life he sought, including a deep satisfaction in art and pottery, but contrary to his expectations, he also gained the world's acclaim as a scientist. He was a Fellow of the American Academy of Arts and Sciences, honorary member of many foreign geological societies and President of the 7th Congress of the International Quaternary Association.

Professor Flint leaves his devoted lifelong partner, Margaret C. H. Flint, a daughter, Anne Ogilvy, three grandchildren, one great grandchild, and a host of admirers, friends, and colleagues the world over.

A. L. Washburn

announcements

Appointment

Dr J. Ronayne to the Chair of History and Philosophy of Science at the University of New South Wales.

Professor Charles Antony Richard Hoare as Professor of Computation at the University of Oxford.

Dr Theodore Morris Sugden, Master of Trinity Hall, Cambridge, will be made President Elect of the Chemical Society in April 1977.

Professor Edward A. Smuckler as Chairman of the Department of Pathology, at the School of Medicine, UC-San Francisco.

Awards

The Paul Ehrlich awards for cell research have been given to **Professor John Gurdon,** of the Institute for Molecular Biology, and **Professor Torbjoern Caspersson,** of the Kungliga Karolinska Mediko-Kirurgiska Institutet, Stockholm.

The Royal Society Mullard Award for 1976 has been given to **Dr G. H. Hitchings,** recently retired from Burroughs Wellcome Co., for his work on chemotherapy, particularly the development of the drugs trimethoprim, allopurinol and azathioprine.

The Royal Society Esso Award for the Conservation of Energy has been made to **Mr. T. B. Jackson** of Honeywell Ltd.

The Ramsay Memorial Fellowships Trustees have awarded their General Fellowship to **Dr M. W. Evans** of the University College of Wales, Aberystwyth and the Netherlands Fellowship to **Dr M. R. Egmond** of the University of Oxford.

Meetings

September 22–24, **Systems and Models in Air and Water Pollution,** London (The Institute of Measurement and Control, 20 Peel Street, London W8 7PD, UK).

September 28–30, **Cellular Aspects of Neoplasma,** London (Dr Gisele M. Hodges, Department of Cellular Pathology, Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2A 3PX, UK).

September 29, **Radioisotopes in Cardiology,** London (The General Secretary, British Institute of Radiology, 32 Welbeck Street, London W1M 7PG).

October 7, **Biology of the Pycnogonida,** London (The Executive Secretary, The Linnean Society of London, Burlington House, Piccadilly, London W1V 0LQ, UK).

Person to Person

Conoco Ltd announces the setting up of The Conoco Lecture on the Responsibility of Industry towards the Environment. The Conoco Lecture, which will become an annual event, will be presented to an invited audience in the spring of 1977 and will be submitted to the appropriate journal in the usual way. The Lecturer will have about four months to prepare his work and will receive a research award of £1,500. Nominations must be received by September 30, 1976.

Wanted, three- or four-bedroom flat or house, preferably furnished, in the West London area near to Ducane Rd. Will exchange for a three-bedroom flat in Turku, Finland from about October 25, 1976 to March 25, 1977. Replies (by September 20, please) to Docent Lauri J. Pelliniemi, M.D., c/o Shirley J. Green, Department of Histo-chemistry, Hammersmith Hospital, London W12.

Will send, for postage, small quantity of **Sophora chrysophylla** seed to persons interested in tropical highlands. Leguminous tree, frost tolerant, good timber, to 10 m high and 50 cm diam, Hawaii native. Perhaps of value in regions with climates similar to Quito, Ecuador. Apply to: W. Cook, PO Box 22364 Honolulu, HI. 96822.

Anyone going to Moscow who would like further information on the Moscow Seminars (see *Nature,* August 19) should contact: Joan Dale, Medical and Scientific Committee, 2 Frognal Rise, London, NW3.

There will be no charge for this service. Send items (not more than 60 words) to Martin Goldman at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

October 14–19, **Warm Water Zooplankton,** Goa, India (Dr S. Z. Qasim, Director, National Institute of Oceanography, Dona Paula, PO Caranzalem, Panaji, Goa, India).

November 10, **Gerontology,** London (The Hon. Secretary, British Council

for Ageing, c/o The National Corporation for the Care of Old People, Nuffield Lodge, Regent's Park, London NW1 4RS).

September 5–9, 1977, **24th International Field Emission Symposium,** Oxford (Dr G. D. W. Smith, Dept of Metallurgy and Science of Materials Oxford University, Parks Road, Oxford, UK).

December 12–14, 1977, **Monitoring Hazardous Gases in the Working Environment,** London (Deadline for abstracts: January 31) (Dr John F. Gibson, The Chemical Society, Burlington House, London W1V 0BN, UK).

March 29–April 1, 1978, **Conference on Sub-Millimetre Waves,** Guildford, UK (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1 8QX, UK).

August 16–23, 1978, **Plant Pathology,** Munich (Congress Plant Pathology, Biologisches Bundesanstalt, Messeweg 11/12, D 3300 Braunschweig, FRG).

Dream to reality in 25 years?

THE photocopier could hardly be called an unmixed blessing of 20th-century civilisation, but few would deny the substantial benefits it has conferred—or the number of jobs it has rendered unnecessary. Aware of the substantial cost (in foreign exchange) of photocopiers, the Indians set about designing one which could be produced by their domestic industry. In terms of the quality of copy delivered, the prototype devised at India's National Physical Laboratory in New Delhi, was as good as any model produced elsewhere. But, the innocent Western visitor asked, why is the loading of paper, the mounting of the material to be copied, the passage of exposed paper through developer still done by operators? Surely if you can apply high technology to the reproduction process, you can apply it to all other things going on in the machine. In our office the secretary just presses a button.

The reply to this rather insensitive question epitomises the dilemma of science and technology in the developing world—to make machines too automatic is to put people out of work, and the unemployed cannot look to a generous social welfare system to tide them over. Better a man employed on a modest wage doing a monotonous job; after all there is no shortage of manpower.

Such machines *versus* men, productivity *versus* employment issues have, of course, been raising themselves in a variety of guises all over the world for nearly two centuries, but this instance neatly illustrates the sort of clash in values that has endlessly to be resolved when developed technology encounters the developing world. These thoughts were occasioned by an important and little-reported lecture given, last week, by the Commonwealth Secretary-General, Mr Shridath S. Ramphal, former Attorney-General of Guyana, to the Science Policy Foundation in London.

Mr Ramphal's theme is that policymakers should be asking "what kind of science policy will contribute most to the eradication of poverty through a process of self-reliant economic advance that is consistent with social justice, environmental harmony and popular participation?" It is "appropriate technology" that should be at the centre of the development debate, not technology transfer. Technology, claims Mr Ramphal, is like genetic material in that it bears the code of social values of the society in which it was produced and sustained—export the technology to a region where the social values are different and it may even prove counterproductive.

A science policy in the developing world that is closely allied to, indeed subservient to, social policy, is not without its problems, as Mr Ramphal recognises. There are bound to be many scientists whose interests could never be channelled in socially useful directions, and yet it would be disastrous to start a witch-hunt to hound all genuine intellectuals out and into the first job available in the developed world. The problem here is in differentiating between the distinguished thinker whose very presence at a particular university or laboratory raises the overall quality of the work done and students produced there, and the hanger-on who attempts Western-style research incoherently and inconsequentially (Mr Ramphal's words).

Another major difficulty is the small size of many developing countries. Sixty of them have populations of less than 5 million, so the rapid accumulation of a "minimum critical mass of scientific talent" committed to well defined social values is not going to be easy. Ideally, regional centres and policies could be evolved, but the scientist's famed supranational spirit often means in reality regular trips half way round the world rather than just over the border.

Nor, Mr Ramphal points out, can the developed world stand back and let the developing world try and work it out alone—"the internal values of the world scientific community cry out for change . . . development [should] be the substantive goal of the science policy of the industrial world".

Many will believe that the case made, while strong on idealism, is weak on realism. The scientific community, pushed into being a tool of social policy, might react in a thoroughly conservative way amid cries about pursuing excellence for its own sake and truth wherever it may lead. And yet evolution is occurring, particularly among young scientists, in their views on the functions of science. Provided the pace does not carry things too far towards revolution, and provided that ideologists are not allowed to make all the running, thereby deterring many excellent but apolitical scientists, there is a real chance that what today seems like an unlikely dream for the developing world could, by the year 2000 be an effective reality. The issue is worth wider discussion in the developed world than it has so far received. □

Silk purse for sows' ears?

Managing Director **W. Makinson** exposes the workings, triumphs, and failures of the UK National Research Development Corporation (NRDC)

DESPITE the occasional protestation to the contrary the university inventor is accorded an important and respected status among the NRDC's clients. Without his contributions it is doubtful whether Sir Stafford Cripps' concept of a statutory body for promoting technical innovation would have survived the political events of the late 1960s and early 1970s. During the corporation's life, however, the attitudes of central government and the universities to research and its industrial application have changed markedly. The declining status of Britain in international trade, and, in particular, the failure of its manufacturing industry to compete with those in other developed countries has underlined the need to promote and utilise university research. The creation of wealth is arguably as important as the pursuit of knowledge, even at the expense of traditional academic freedoms. The NRDC's task, as defined in the 1948 Development of Inventions Act, is to assist in the transfer of new technology from the laboratory to industry, and because the corporation aims to be self-financing it has adopted arrangements that provide wherever possible for the recovery of the costs incurred.

It is hardly surprising, therefore, that the role of the NRDC in universities has come in for some critical examination. Those affected by new constraints, and those strongly motivated by the wish for closer and more productive relationships between academic and industrial communities, retain a deep interest in the directions followed by the organisation. This reappraisal has led to suggestions that technology emerging from universities might be better exploited by other routes than those offered by the NRDC itself.

There could be grounds for this new attitude. Some inventors are industrially oriented and have enough familiarity with legal, patent and commercial matters to go it alone. But they are rare. Experience shows that there are proven advantages in adopting a professional, centralised approach to exploitation, particularly where new technology is of international significance. Successful exploitation requires a careful blend of talents and resources: professional skills, a wide knowledge of industry, financial resources, an ability to assess and take risks and, on occasion, some ruthlessness in decision

taking are all essential. This is often not appreciated by academic research workers, to whom the invention is the major event rather than the starting point of a process fraught with problems and pitfalls, many of which he is neither qualified nor equipped to meet alone.

Moreover, experience also indicates that the majority of inventions turn out to have little commercial potential, however professionally they may be handled. And, paradoxically, it is the almost quixotic willingness of the NRDC to devote time and money to university cases which probably do not justify support and consequently fail, that has led to criticism. This cannot be lightly brushed aside, however: the corporation needs to retain the confidence of the academic research community.

Patent protection

The NRDC plays a crucial role in both establishing and protecting industrial development that may arise out of basic research. The world of patents is now so complex and has so many ramifications that it cannot be effectively handled without the aid of the specialised professionals. Industry can, in some fields, get by without patent protection and can penetrate markets simply through dynamism, confidential know-how, and competitiveness. Where the element of innovation is high, however, companies usually insist on adequate patent protection for as long as possible after products become established. This is especially true in the case of, for example, pharmaceuticals.

The executive officers of the NRDC are well supported by commercial, legal and patent services on a scale which compares favourably with all but the largest multinational companies; its patent department, for instance, is among the largest in the United Kingdom. These expert advisory services are available to university inventors even if they are not already clients; the earlier an enquiry is made, however, the more useful any advice is likely to prove.

Once an inventor has placed himself in the hands of the NRDC he must accept certain limitations. He is less free to dictate the subsequent course of development and exploitation, while his share of any subsequent revenue is inevitably cut. This may conflict with a

drive for recognition through immediate publication; it may also preclude direct personal arrangements with individual companies, even though that could be the most obvious route to early exploitation. Existing or future patent rights are assigned to the NRDC, and equity is maintained through a revenue-sharing agreement which divides proceeds from licence royalties or other income between the corporation and the university concerned (or the inventor). Under current arrangements, the rights to inventions arising from projects funded by UK research councils have, in most cases, to be assigned to the NRDC anyway.

The time that the NRDC takes to decide whether support is worthwhile has occasionally been a source of frustration. But some delay is inevitable. Potential markets must be properly assessed, as must the potential patent strength. Regrettably, the more commercially attractive propositions are more likely to run up against established competition. But throughout, the corporation maintains close contact with the inventor.

Finance for development

Unlike foreign government agencies with similar responsibilities, the NRDC can provide funds not only for research programmes which may eventually prove of commercial significance, but can also support the further development of inventions already made. Indeed, if the support for further development were not available it is likely that many university inventions could not be effectively exploited. Bearing in mind the NRDC's reserve borrowing powers and currently favourable financial status, there is, within reason, no upper limit to funds available for any particular project, as long as it can be effectively deployed. The slogan adopted by the corporation in 1973 : "£1,000,000 available for university research", is no idle statement.

The corporation always seeks the most effective route to commercialisation, so it usually attempts to involve an appropriate industrial organisation from the outset, either as a potential licensee and/or as a joint source of development funds. Negotiations may be carried out either by the university or the company, or both. It is quite normal for an inventor to act as a consultant on mutually acceptable terms.

Failure to arouse industrial interest in a particular project might often indicate that attempts at exploitation should be abandoned. On the other hand, it could be simply that a lack of sufficient evidence (in the form of a working prototype, for example, or of credible test results) is the only reason why industry cannot be persuaded that

an innovation is of importance—this is the "predevelopment gap" referred to in the Richards Report to the Engineering Board of the UK Science Research Council. While such a gap can be bridged by NRDC funds, the corporation will not shell out extra support merely to keep inventors happy; nor will it support an unnecessary research team, however competent. When further work is carried out in a university at the NRDC's cost a portion of any royalties is usually set aside to offset these expenses.

NRDC contributions to company development costs are recovered separately through a levy on subsequent sales of products exploited. The levy is calculated to provide a return reasonably related to the risks involved. The terms have from time to time been criticised as harsh, particularly when applied to proposals submitted by embryo, campus-based companies set up to exploit the results of research projects undertaken in a particular university. The criticism should be viewed against the statistical record, however, which shows that in three out of four cases the NRDC fails to recover its investment.

The corporation does not provide grants for company support, nor does it undertake to provide general working capital, except where an identified invention is involved. Companies must in such cases seek other sources of finance and accept the terms and conditions normally associated with them. It is worth noting, however, that support by the NRDC does not inhibit companies from qualifying simultaneously for other types of government assistance, nor need NRDC funding rank as a contingent liability where bank overdrafts or term loans are concerned.

Track record

Since its inception the NRDC has received about 5,000 proposals from universities, and taken assignment in about 2.000 cases. This compares favourably with the overall national picture including all sources of support —34,000 proposals and 6,000 assignments. So far, of the 2,000 university inventions supported by the NRDC about 200 have emerged as revenue earners; over the past five years this is about one out of every five or six submissions. The cumulative income attributable to university research is about £15 million, of which about £8 million has been recouped by the NRDC revenue-sharing agreements.

At present, the NRDC is involved in about 90 development projects involving universities, representing a total investment of about £1.5 million, about £1 million of which is actually being spent with the inventors. The largest single current commitment is that with
The Dracone, a soft failure

the Southampton Institute of Sound and Vibration Research where £160,000 is devoted to research into techniques to produce light-weight quiet, diesel engines.

By far the most conspicuously profitable inventions so far have been those made 20 years ago by research workers in the Sir William Dunn School of Pathology at Oxford in collaboration with the Antibiotics Research Station of the Medical Research Council. The work involved led to the discovery of the drug Cephalosporin C and the subsequent isolation and identification of its nucleus; worldwide licensing arrangements currently provide approximately 80% of the corporation's total annual royalty income. Other significant 'winners' would include the anticoagulant Arvin (Penang and Oxford), portable heart/lung machines (Royal Postgraduate Medical School), peptides derived from bee venom (University College, London) and methods of extracting diosgenin (the starting material for steroids used in the contraceptive pill) from fenugreek (Nottingham). Perhaps the most notable engineering inventions were those of Manchester University relating to computers.

More recent developments for which high hopes are sustained include improvements in electrochemical cells (Newcastle), continuous countercurrent ion-exchange techniques for uranium extraction (Imperial College, London), pioneering work on high modulus polymers, and novel flotation columns for mineral processing (Leeds), ultrasonics applied to metal-working (Aston), "surround" sound systems (Reading), speckle pattern comparators (Loughborough), and Pole Amplitude Modulation synchronous motors (Bristol). The NRDC has also set up a wholly-owned subsidiary company for the further development and marketing

of Genesys—a civil engineering computer-aided design system (CAD) initially developed at Loughborough University of Technology—and is in the process of creating a second software company for more generalised CAD packages. Though it is difficult to interpret statistics sensibly because of the often long gestation time of really successful inventions, the corporation is confident that the current input from university sources could maintain future royalties at a healthy level.

The NRDC has, of course, had its failures—sometimes spectacular—in its efforts to commercialise technically sucessful inventions. Any listing would have to include Dracones (large flexible floating containers for transporting fluids, based on proposals from Cambridge University) and the Tracked Hovercraft, which used the linear motor. Though the NRDC received no financial returns from either project both 'failed soft' in that the principles developed in these instances have been subsequently applied successfully to other industrial problems. Indeed, the Dracone, originally intended as an alternative to large oil tankers at the time of the Suez crisis, has been used to transport drinking water to the Greek islands, and might still play a useful role nearer home if the present drought persists.

Inevitably, many inventions from academic sources fail for simple technical reasons, usually in the translation from the original concept to practical realisation in commercial or industrial terms. Despite its years of experience, the corporation has no crystal ball; it will go on, no doubt producing more sows' ears than silk purses, but it has no intention of withholding support and encouragement wherever the rewards seem likely to justify effort and expense.   □

Treading softly on the ozone layer

A long-awaited report on the environmental effects of halocarbons was published in the United States last week. Colin Norman and Chris Sherwell report from Washington

THE US National Academy of Sciences (NAS) last week added its powerful voice to the scientific and political dispute about whether halocarbons, spewed into the atmosphere chiefly from aerosol spray cans, are causing serious damage to the Earth's ozone layer. The general press seemed to have some difficulty in deciding just what message the Academy was trying to convey, however. "Scientists Back New Aerosol Curbs to Protect Ozone in Atmosphere" ran the headline in the *New York Times*. "Aerosol Ban Opposed by Science Unit", said the *Washington Post*. Both were in fact correct, and the contrast reflects the finely balanced nature of the Academy's conclusions and recommendations.

The chief conclusion, set out in a long-awaited report by the NAS Committee on Impacts of Stratospheric Change, is that significant deterioration of the ozone layer will eventually occur if halocarbons continue to be released at their present rate. That would allow more ultraviolet radiation to reach the Earth's surface which, in turn would cause additional cases of skin cancer and other biological damage. Moreover, the committee warned of a possible effect on the world's climate from any continuing build-up of halocarbons in the atmosphere.

Alarming though such prospects may be, the committee cautions against taking precipitate action, such as banning the use of halocarbons as propellants in aerosol products. Instead, although it acknowledges that regulation is "almost certain to be necessary at some time and to some degree of completeness", the committee recommends that key uncertainties in the calculations should be cleared up before uses of halocarbons are restricted. The necessary information should be gathered in less than two years, the committee argues, and such a delay will cause little additional damage to the ozone layer.

The NAS recommendations were greeted with restrained enthusiasm by the halocarbon industry, and by the makers of hair sprays, deodorants and similar cosmetic products which together account for the major uses of the material. The industry-sponsored Council on Atmospheric Sciences said in a statement last week, for example, that the report backs the industry's view that "more research is required before any national decision on the fluorocarbon issue can be reached". Some scientists and environmentalist groups were not so happy, however. A spokesman for the Natural Resources Defense Council noted, for example, that the NAS recommendation for a two-year delay in regulation "is a value judgment which scientists are no better equipped to make than anybody else". Clearly, publication of the report will not put an end to the controversy which has been raging over the ozone depletion theory for the past couple of years.

The theory was first advanced in 1974 by two scientists from the University of California, F. Sherwood Rowland and Mario J. Molina (*Nature,* **249**, 810; 1974). They argued, in short, that the very properties which make halocarbons so useful—their insolubility and inertness—also pose a problem : unlike most airborne pollutants, they are not washed out of the lower atmosphere by rain. They gradually drift up into the stratosphere, where they are broken down by sunlight, releasing free chlorine atoms which break down ozone molecules through a complex series of chain reactions.

If that sequence of events is actually taking place, the result would be a reduction in the concentration of ozone in the stratosphere, and a consequent increase in the amount of harsh ultraviolet radiation reaching the Earth's surface. The ultimate consequence would be an increase in the incidence of skin cancer, which is correlated with exposure to sunlight, and possible biological damage to plants and animals.

Publication of the theory ignited a scientific and political controversy as some scientists attacked it as being implausible, while others argued that it is frighteningly realistic. The implications for human health also led to suggestions that the use of aerosol sprays be curbed, and prompted a massive research effort to test the validity of the theory.

Then, earlier this year, yet another alarming theory was put forward, namely, that accumulation of halocarbons in the atmosphere will result in a so-called "greenhouse effect", increasing the Earth's temperature and perhaps altering its climate.

The NAS committee has thus been poring over a mass of information accumulated since Rowland and Molina published their theory, and its report has been delayed for nearly six months by the appearance of important and conflicting pieces of data. In the end, however, the committee concluded that the evidence produced so far supports the ozone depletion theory. According to the committee's Chairman, John Tukey, a statistician from Princeton University and Bell Laboratories, the mechanism is now "a relatively well understood process".

It should be noted at this point, however, that it is impossible to test the theory by direct measurements of ozone concentration in the stratosphere since available measuring techniques are too insensitive to detect relatively small, long-term variations in the ozone layer. The theory is therefore based on laboratory experiments and computer analyses, supplemented with direct measurements of the atmospheric concentration of various key links in the chain reaction, such as chlorine, hydrogen chloride and so on. The whole business is a little like building up a jigsaw puzzle from badly cut and incomplete pieces.

Nevertheless, the committee has concluded that, if halocarbons continue to be spewed into the atmosphere at the rate they were released in 1973, the ultimate effect would be to reduce the concentration of ozone in the stratosphere by about 7%. It will take several decades to reach that level of depletion, however, since once released into the atmosphere, halocarbons can take up to a century to reach the stratosphere to do their work.

The figure of about 7% is deceptively precise. In fact, Tukey was careful to point out last week that it may turn out to be as low as 2% or as high as 20%, the uncertainties being caused by the complexity of the reactions—as many as 30 or 40 may be involved—and by the incompleteness of the information so far accumulated. That's one reason why the committee recommended against an immediate ban on non-essential uses in aerosols and suggested that more data are required.

Even if all release of halocarbons were to cease immediately, the committee has calculated that the material already in the lower atmosphere would continue to rise into the stratosphere and increase the destruction of the ozone layer for at least a decade. The ozone layer would then recover very slowly, with only half of the reduction being restored in 50 years. As for the consequences of delaying regulation by two years, the committee has calculated that if the figure of 7% reduction is correct, "whether a halving in (halocarbon) use and release were to take place in 1977 or 1979 would alter the

ozone reduction at any later date by no more than 1/6 per cent". In other words, "costs of delay in decision are small, not more than a fraction of a percent change in ozone depletion for a couple of years' delay".

Some perspective on the uncertainties in these calculations can be gained from a brief look at the problems which the committee encountered in putting out its report. The report was originally scheduled for publication in April but just as it was being put together, some new information, which seemed to throw the whole basis of the ozone depletion theory out of the window, suddenly came to light. In short, the theory would fall apart if there is a natural process which ties up chlorine atoms before they can attack the ozone molecules in the stratosphere. It seemed for a few weeks that just such a mechanism had been discovered. The suggested mechanism was the formation of chlorine nitrate, a compound which may be relatively stable under stratospheric conditions from chlorine atoms liberated from halocarbons and oxides of nitrogen already in the stratosphere.

When calculated rates of formation of chlorine nitrate were slotted into the equations, it turned out that halocarbons may even have a positive effect on the ozone layer—in other words, they may increase ozone concentration by removing oxides of nitrogen from the stratosphere. Later computations indicated, however, that the assumed rate of formation of chlorine nitrate had been greatly overestimated, and the effect of the mechanism is actually quite small.

As for the potential climatic effects of halocarbons, the committee suggests that precise information is equally hard to come by. Nevertheless, its best guess is that there will be a warming effect due to absorption of infrared radiation by halocarbons in the atmosphere, the effect being similar to that proposed for carbon dioxide accumulated through the burning of fossil fuels. Tukey suggested that the effect from halocarbons in the year 2000 might be about 40% of that due to burning fossil fuels, but he added that the relationship between such warming trends and broader climate changes is very poorly understood. "There are going to be some climate effects and it would be, I think, a disservice to put hard numbers on them this year", he said.

Although the committee recommends against immediate restrictions on the use and release of halocarbons, it does urge a number of steps to prepare the way for regulation should it be needed. At present, the authority to regulate the use of aerosol sprays is vested in at least three different agencies—the Food and Drug Adminis-

tration (FDA) the Environmental Protection Agency (EPA) and the Consumer Product Safety Commission (CPSC)—and it is questionable whether any of them really has a powerful enough mandate to act. Legislation is clearly required. Last week, by coincidence, Congress finally approved the Toxic Substances Control Act, a legislative landmark which, according to some interpretations, may provide EPA with enforceable authority over halocarbons. But the Bill is opposed by industry and may be vetoed by President Ford. Similarly, Congress is close to passing a series of amendments to the Clean Air Act, which again would give EPA a powerful lever to regulate aerosol products. The problem here, however, is that the House and Senate may not be able to settle some basic disagreements on other parts of the Bill before the October 2 recess. Thus, legislation may have to wait until next year.

The committee does, however, recommend one potentially important step which could be implemented relatively quickly. It suggests that aerosol sprays containing halocarbon propellants should bear a label stating that fact. The FDA, which has authority to regulate cosmetics, probably has the power to enforce such labelling. Though the committee argues that

"labeling should in no sense be regarded as a substitute for regulation but rather as an aid to consumer self-restraint", the effect could be rather large, since consumers are already beginning to turn away from some aerosol products. In 1975, for example, the use of halocarbons declined by 15% —the first decline in more than a decade (the accompanying table shows 1975 figures).

As for the effects on industry of a ban, the committee says they would be "appreciable". Just how appreciable can be gleaned from the fact that total world production of the two halocarbons with which the committee is concerned—namely, $CFCl_3$ or F-11, and CF_2Cl_2 or F-12—amounted in 1974 to nearly one million tonnes. But, says the committee, the industrial consequences do "not loom large" against the background of "a possible, although very small, change in world climate".

Finally, it should be noted that the US accounts for almost half the total world use of halocarbons. Thus, if the US Government decides on regulation, it would only attack half of the problem. The committee therefore recommends that other countries should be encouraged "by whatever appropriate means are likely to be effective" to take similar action.   □

Estimated worldwide releases of F-11 and F-12 in 1975 (millions of pounds)

Aerosols **1115.1** (74.5%)	Personal	Antiperspirants/deodorants		458.4
		Hair care		401.5
		Medicinal		37.3
		Fragrances		2.3
		Shave lathers		0.9
		Others		34.4
	Household	Room deodorants		17.7
		Cleaners		9.6
		Laundry products		23.4
		Waxes and polishes		9.2
		Others		9.2
	Miscellaneous	Insecticides		33.3
		Coatings		22.9
		Industrial		39.0
		Automotive		8.0
		Vet. and Pet		2.3
		Others		5.7
Air conditioning **refrigeration** **204.7** (13.7%)		Mobile air conditioning		89.8
		Chillers		42.9
		Food store		33.1
		Beverage coolers		5.8
		Home refrigerators and freezers		5.8
		Miscellaneous		27.3
Plastic foams **176.5** (11.8%)		Open cell		100.0
		Closed cell		76.5
			Total	**1496.3**

Figures are based on the annual incremental releases of F-11 and F-12 indicated for 1975 in a 1976 report by the Manufacturing Chemists Association, and the detailed percentage analysis by users in the US for 1973 in a 1975 report by Arthur D. Little, Inc. for the EPA. Figures do not include USSR and Eastern Europe.

Breakdown between F-11 and F-12 not available. If F-11($CFCl_3$, 77% chlorine by weight) could be replaced by an equal weight of F-12 (CF_2Cl_2, 59% chlorine by weight)—not often feasible—the amount of ozone reduction would be decreased.

Recipe for less disaster

The first ever report of the recently formed UK Advisory Committee on Major Hazards (CMH), which recommends improved safety measures for potentially hazardous industrial installations, was published last week. Alastair Hay reports

THE new measures advocated in the CMH report* could provide a framework for the safer building and siting of industrial plants in Britain. The report considers the hazards of "explosion, the sudden release of toxic substances (and) cataclysmic fire", and industries that would come under closer scrutiny include those producing fertilisers, explosives, petrochemicals and nylon and other polymers. Nuclear installations are not considered in the report.

The report is the first of its kind to be produced as a result of a government commission in any country. The CMH was appointed by the Health and Safety Commission (HSC) following the disaster at the Nypro chemical plant at Flixborough in June 1974, which killed 28 people, injured more than 100, and resulted in an estimated £28 million worth of damage to the immediately surrounding area. The Flixborough explosion was the most devastating in Britain since the end of World War II.

Prominent among the report's 38 recommendations is a call for a notification scheme that would allow the UK Health and Safety Commission (HSC) to identify particularly hazardous installations. In drawing up a list of notifiable installations the committee identifies 8 different types of plant, but ignores nuclear installations, in line with its original brief. An estimated 1,000–3,000 sites at present operating within the UK would fall within the proposed list, of which at least one in ten is operating to safety standards giving possible cause for concern, the report suggests. Moreover, while potentially notifiable plants are distributed throughout the UK, the report identifies specific areas of concentrated development such as Teesside and Canvey Island where a chain reaction of explosions might pose an additional hazard. The proposed list of notifiable installations includes:

● those storing or processing toxic material where there could be an emission of toxic gases or vapours equivalent in effect to more than 10 tonnes of chlorine.

● those storing or processing flammable materials where there could be a rapid emission of more than 15 tonnes of flammable gases or vapours.
● Those storing or processing more than 5 tonnes of materials which are intrinsically unstable or of very high exothermic reactivity. Examples are ethylene oxide, acetylenes, and organic peroxides.
● Those with a large inventory of stored pressure energy, operating at 100 bars or more, using gas phase reactions.
● Those storing or processing more than 10,000 tonnes of flammable materials with a flashpoint of less than 22 8 °C.
● Those storing or processing more than 135 tonnes of liquid oxygen.
● Those storing or processing more than 5,000 tonnes of ammonium nitrate.
● Those storing or processing materials which during a fire could cause an emission of toxic gases or vapours equivalent in effect to more than 10 tonnes of chlorine.

The list would apply to both existing and proposed installations, though the CMH has stressed that it is only provisional, and that a future list will almost certainly be wider ranging.

The report underlines the increasing importance of getting design and operating procedures right the first time. "Because of their present-day size and throughput," the report says, "there are now many plants throughout the world where a critical first mistake can result in disaster". Moreover, the committee warns of the increased dangers to local communities: the report notes that while "the probability that an individual worker will be involved in a fatal accident has notably fallen, the chances [of] a plant failure . . . involving the public at large . . . [have] become considerably greater".

Some of the specific proposals included in the report stem directly from recommendations made by the court of inquiry into the Flixborough disaster. For instance, the report advocates that industrial pipework, valves and pumps, at present often only tested before assembly, should also be tested following installation, when they form part of a total pressure system. It also recommends that any changes in the operating procedure at plants should be reported to the HSC for evaluation. Control rooms—that at Flixborough, built of brick, was completely destroyed in the explosion—should be single storey, reinforced concrete buildings, situated in a relatively safe area, while black box recorders similar to those used in air-

craft, should be introduced to monitor plant operations, allowing the identification of fault sequences leading to accidents. Moreover, safety officers should have easy access to international data banks on industrial accidents and plant safety features, the report says.

The report advocates closer consultations between local authorities and the HSC when planning permission for new industrial plants is being considered. Neighbouring authorities likely to be affected by final decisions should also be included in the discussions. But the CMH has not yet considered the consequences of closing down potentially hazardous sites already in operation. At present, the compulsory closure of existing plant involves local authorities in the payment of considerable sums in compensation. The committee plans to discuss this problem with the Department of the Environment.

The Report does not advocate the enforced notification of 'near misses', which, it feels, could inhibit the flow of information. Mr James Tye, director of the British Safety Council, welcoming the report, estimated that for every fatal accident in British Industry, there are three involving injury to workers, thirty resulting in damage to plant, and six hundred 'near misses'. Nonetheless, both industry and the HSC recognise that the lessons to be learned from a 'near miss' are as valid as those gained in the wake of a full-scale accident.

Professor Bryan Harvey, Chairman of the CMH, stressed the responsibility of management in introducing appropriate safety measures even before they became compulsory. Industry, he said, would in future have to give far more consideration to safety factors. Speaking for the chemical industry, Mr Donald Bennett, Chairman of the Chemical Industry Safety and Health Council, welcomed the report as "broadly consistent with the industry's own thinking on the form of control required". But he singled out areas needing further investigation, among them "the definition of the unit of notification", what parts of plants, processes or sites should be licenced, and the problem of selecting "truly independent experts" to act as arbitrators between industry and the HSC.

Mr Bennet's sentiments are not inconsistent with those of the CMH itself, outlined in the introduction to the report. The committee acknowledges the need for further discussion and research, and admits to the preliminary nature of much of the work completed so far; the report has been distributed to various interested organisations with requests for specific comments on the committee's proposals. □

BRAZIL

CONCERN for the environment is increasing in Brazil, a country which until recently dismissed ecological preoccupations as detrimental to industrial development. But even though public consciousness about the environment in this vast nation of 110 million people has been raised, little has been achieved in practical terms, and the environmental battle is far from won.

On the plus side, however, a new Presidential-level, environmental protection office—known as SEMA—has been authorised to veto state financing of industrial undertakings lacking adequate pollution safeguards. The head of SEMA, Paulo Nogueira Neto, regards this as a major victory for the environmental protection movement. And he does not believe it will be very hard to persuade Brazilian industry to fight pollution before producing it "The inclusion of antipollution equipment in an industrial project usually adds only 2% to the project's total cost", Nogueira Neto declared recently. "On the other hand, if a factory is ordered to install antipollution equipment after it already has gone into operation, the cost of such equipment will be much higher." (There's a major catch to this, however : SEMA does not yet have adequate authority to shut down existing transgressors, and cannot force them to install antipollution gear.)

Also on the plus side, the Federal Government's much criticised and undermanned Forest Service has scored some recent successes in catching clandestine hunters, and in preventing the export of hides of illegally slaughtered protected species such as deer, monkeys and alligators. The Forest Service plans to burn 100,000 recently apprehended pelts and skins, hoping to deter future unlicensed hunting. Most illegal hunting takes place in Mato Grosso State and the Amazon Jungle, which, because of their immense size and lack of roads and communications, are practically impossible to patrol.

The Forest Service has also won a victory of sorts by successfully fining the Brazilian subsidiary of Volkswagenwerk AG the equivalent of $25,000. Volkswagen has gone into the cattle ranching business in the Amazon Jungle, taking advantage of liberal Brazilian tax incentives. The fine follows a technical violation concerning the clearing of trees on Volkswagen's property: The Forest Service at first wanted to fine Volkswagen the equivalent of more than $5 million for the alleged un-

authorised felling of some 9 million trees, but the plan was reportedly shot down at higher levels within the government, which wants to maintain a favourable climate for foreign investment.

On the minus side of the environmental picture, nearly 2,000 residents of a slum district in the north-eastern city of Salvador were hospitalised after breathing potentially deadly chlorine gas from a chemical plant. The plant is an indirect subsidiary of Petrobras, the state oil company, and will probably escape with only a fine.

Salvador is, in fact, apparently a major target of industrial polluters. The neighbouring Atlantic Ocean and several rivers in and near the city are becoming poisonous repositories of mercury, cadmium, sulphuric acid and ferrous sulphate. Jun Ui, a Japanese expert, has studied the situation in Salvador and concluded that the population is on the verge of mass poisoning, similar to the mercury poisoning that caused a scandal in Minamata, Japan, during the 1950s. Professor Ui has found traces of mercury in the hair of Salvador residents, and has said that cadmium in the region could cause bone disease.

People in several Brazilian cities have begun to band together to agitate for the preservation of urban green space; so far, however, none of these groups have been very effective. In Sao Leopoldo, a suburb of Porto Alegre, schoolchildren recently held a public demonstration against the felling of stately palm trees within the school grounds. The Forest Service fined the school administration and ordered it to stop, but not before 25 coconut palms had fallen to the chain saw. In Belo Horizonte, a growing city of 1.5 million people that is rapidly turning into a "concrete jungle", citizens meanwhile took to the streets to protest against the felling of a grove of trees on Church land.

But the Church obtained permission to continue the clearance, and now plans to build a shopping centre and office building on the newly stripped site.

● An antismoking lobby has emerged in Brazil. The Rio Grande do Sul State Medical Association has managed to scrape up the equivalent of $40,000 for a three-month advertising campaign warning of the health hazards of smoking. It aims to persuade the Brazilian news media to carry antismoking propaganda to offset cigarette advertising. There is also pressure for government health warnings on cigarette packages and tobacco advertisements. The antismokers face powerful adversaries. Brazil's cigarette industry, dominated by a subsidiary of the giant British-American Tobacco Company, is one of the biggest advertisers in the Brazilian news media, and pays more than $1,500 million in Brazilian taxes each year.

● Brazilian petroleum engineers have always believed that there is oil in Brazil's Amazon region, a belief not generally shared by the world's oil industries. Now, however, Petrobras has found oil off the coast of the far northern territory of Amapa, and along the continental shelf off Rio de Janeiro State. It is still too early to tell how much oil may be in the area of the test-well but the fact that Brazil has finally discovered Amazonian oil is important in itself. Brazil, whose principal domestic source of oil is the north-eastern state of Bahia, still imports 80% of its annual oil requirements, which causes serious balance-of-payments problems. Five international oil corporations plan limited prospecting operations in Brazil.

● A Brazilian obstetrician is encouraging his patients in the prosperous middle-class city of Curitiba, in the southern part of the country, to have their babies in the same way as the native Indians: squatting instead of lying down. Dr Moises Paciornik has studied primitive Indian tribes in Brazil and has concluded that squatting births lead to less pain and fewer postnatal complications. Once contractions have started, delivery is safer and quicker, if gravity is allowed to help, Dr Paciornik says. He has adapted one of the delivery rooms in his Curitiba clinic for squatting births, complete with an Indian-style mat on the floor, and he says his urban patients show surprisingly little reluctance about giving birth the Indian way.

Bruce Handler

IN BRIEF

Electric cars for US

Congress last week won a small, but important, skirmish with the Ford administration over a plan to develop an electric car industry in the US. It overrode a Presidential veto on a Bill to devote up to $160 million to research, development and demonstration of electric car technology over the next six years. The key part of the Bill—and the part which stuck in Mr Ford's throat—is a scheme to create a market for electric vehicles through direct government support. In the next three years, the Government is empowered to purchase up to 2,500 electric vehicles, with a further 5,000 within five years. Mr Ford had vetoed the legislation feeling that the technology was not sufficiently advanced for a subsidised purchasing programme of that size.

Engineers building up

For all that is being said about the sad state of recruitment into engineering, figures just released by the Universities Central Council on Admissions (UCCA) show a steady growth in the number of applicants, and admissions, to universities for engineering courses (Statistical Supplement to the Thirteenth Report, 1974–5, UCCA, £1.25). Since 1973 electrical civil and mechanical engineering have each registered gains in applicants—firm figures for 1975, and reliable forecasts for 1976 show that in three years engineering has gained 30% more applicants. Mathematics, physics and chemistry remain in the doldrums; chemistry was a few per cent up both in 1975 and 1976, but physics dropped several per cent in 1975 and just held its ground in 1976.

Soyuz in orbit

Carrying photographic equipment developed partly by the East German company Carl Zeiss (Jena), the latest Soviet space-shot, Soyuz 22, went into orbit last week. Special emphasis is being paid to the photography of large tracts of Soviet territory, and while practical results are anticipated—similar, it is hoped, to those from the Soyuz 12 survey which revealed potential oil- and gas-bearing zones in the region of the Mangyshlak and Buzachi peninsulas—the main aim is to develop new techniques. Additionally, as a follow-up to earlier experiments during which cultures of *Proteus* bacteria grown in space showed signs of developmental deviations, experiments aboard Soyuz 22 have been designed to investigate the phenomenon.

SCIENTIFIC meetings used to be almost routinely enlivened by projectionists who inserted slides upside down, backwards, and so on. But the introduction of carousel projectors has largely done away with this form of amusement, especially when the lecturer is artful enough to load the slides in advance. I always try to meet projectionists ahead of my talks. Most of them are males, often students who take the job as part-time employment. I usually scrutinise the projection booth for copies of *Sports Illustrated* and soft-core porn magazines, which I scan briefly to soothe my nerves. If present, such reading matter shows that the projectionist will not be listening for slide-changing cues during my lecture, and I know that I must shout my requests.

One of my adventures as a lecturer had an almost dream-like quality. It was in Las Vegas. I arrived at the "meeting hotel" to speak to a convention of dietitians. After threading my way past slot machines and blackjack tables, I found that the theme of the day was "Nutrition in the Age of Aquarius". The delegates wore emblems proclaiming their zodiacal signs. Some of them were multiparous married women whose badges stated "I am a Virgo", which seemed incongruous to me. The slide projector had somehow been overlooked, and it was one hour to launch time. A hotel employee was delegated to drive me on a hunt for the machine. We bowled along a road that headed west, past shacks, into the relentless desert landscape until I realized that we were well on the way to Death Valley. Eventually we backtracked and spotted a Quonset hut that yielded a pro-

jector, and we got back to the casino in time. I was so stimulated by the experience that I preceded my lecture with an impromptu summary of my unvarnished opinion of the zodiac and of horoscopes.

Previously in these pages, I have described the incident in which

Slide slips

THOMAS H. JUKES

Marianne Grunberg-Manago disappeared from sight at the start of her lecture, in a manner similar to the descent of Erda in *Das Rheingold*. I made a mistake; I have received a peremptory letter of reprimand from the head official of the American Society of Biological Chemists, pointing out that it happened in Philadelphia in 1958 rather than in Atlantic City in 1963. Another correspondent, more sympathetic, says that he re-

members that Marianne blew kisses and waved to the audience as the platform went down. Be that as it may, I recall another Federation Meeting—I think it was in Chicago—addressed by Larry Irving, in which some interesting slides were shown at a long lecture on respiratory physiology. They were remarkable for all being projected sideways. The large audience developed a transient form of torticollis resembling a sort of a lateral whiplash injury. I believe that the explanation for the misoriented slides had a nationalistic background. It seems that British slides used to be $3\frac{1}{4}''$ square, American slides $3\frac{1}{4}'' \times 4''$, while the Canadians, with their altogether admirable trait of self-assertiveness, used slides that were $4''$ square. The slides in question must have been prepared by a Canadian for showing in US projectors, which the Canadian evidently thought received $3\frac{1}{4}'' \times 4''$ slides vertically rather than horizontally.

One of the new amenities is an antenna that is coiled around the lecturer like the string around a parcel. I canot vouch for the following story that was related to me, but even if it didn't happen, it has obvious possibilties for users of Citizens Band radios. An unfortunate scientist swathed in his antenna, switched on the microphone and started his talk. Or tried to. But instead of the lecturer's voice the equipment picked up, on the same wavelength, the thunderings of a fire-and-brimstone preacher at a nearby revival meeting. I am told that the scientist plucked the offending antenna from his body in a vain effort to quell the interruption.

X-ray cryoenzymology

from C. C. F. Blake

ALTHOUGH the degree of knowledge constituting an "understanding" of the catalytic power of enzymes may be a matter for debate, the basic nature of certain kinds of information is not in dispute. These essential pieces of information include the three-dimensional structure of the enzyme, and especially its active site; the sequence of enzyme–substrate intermediates that occur along the reaction pathway, their individual structures, and the energetic relationships between them. Clearly no single technique can provide information at the level required on all these topics, and a synthesis of data from several disciplines is necessary before correct answers in a very difficult field can be expected.

The contribution of X-ray diffraction, as the unchallenged technique for the determination of three-dimensional structure, would seem to lie in principle in defining the structures of the native enzyme (with essential aid from sequence studies) and the enzyme–substrate intermediates. But, despite great success with the enzymes themselves, structures of true, productive intermediates have proved elusive. The reason for this is that at room (or physiological) temperatures there is such a gross inequality between the rapidity of the enzyme reaction even in the crystalline state, and the length of time required to complete an X-ray experiment, that there is no possibility of success. The only productive intermediates that can possibly be examined in normal conditions are the Michaelis complexes of certain enzymes whose reactions and equilibrium constants are favourable.

The inability to look at true enzyme–substrate intermediates has not prevented X-ray diffraction from producing some important results on the activity of certain enzymes, for example, lysozyme, the serine proteinases and carboxypeptidase. With these enzymes, results from the study of the interactions of inhibitors or virtual substrates could be extended by structural and chemical considerations to produce plausible models of the productive complexes, from which generally accepted hypotheses of their hydrolytic activity have been deduced. However, the intracellular metabolic enzymes that are now under study have so far resisted this approach, presumably because their more sophisticated mechanisms are not so amenable to chemical intuition. In this context the two papers in the current issue of *Nature* (Fink and Ahmed, page 294 and Alber, Petsko and Tsernoglou, page 297) on the formation and X-ray analysis of stable, productive enzyme–substrate intermediates at very low temperatures, represent a radical departure of great promise.

It has long been known that many enzymes are catalytically active at sub-zero temperatures. Douzou, in his pioneering studies of enzymes at low temperatures (Douzou *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **66**, 787; 1970), has shown that true enzyme–substrate intermediates can be isolated in a stable form at very low temperatures if sufficient care is taken with the physicochemical properties of the aqueous–organic solvent systems that are necessary. In view of this Fink and Ahmed have investigated the behaviour of chymotrypsin, trypsin and elastase towards specific ester substrates at temperatures between −20 and −70 °C in aqueous–organic solvents, to test the feasibility of obtaining stable crystalline intermediates of these enzymes suitable for X-ray studies. They show that in these conditions the rate of acylation is several orders of magnitude faster than the rate of deacylation, and that for each enzyme, conditions can be achieved in which the rate of deacylation becomes so low that acyl-enzyme intermediates accumulate to high concentrations. At temperatures of −50 to −70 °C in aqueous dimethyl sulphoxide or methanol at *p*H values of maximum activity, they have prepared well-defined acyl-enzyme intermediates in almost stoichiometric quantities, for all three enzymes both in the dissolved and crystalline states. These intermediates are stable for periods of days to months at low temperatures, but when warmed up to 0 °C they are turned over at the expected rate.

A preliminary X-ray analysis of one of the stable acyl-elastase intermediates characterised by Fink and Ahmed is reported by Alber, Petsko and Tsernoglou. Elastase was chosen because its active site is accessible, and it exhibits low solubility and high stability in the aqueous methanol which is necessary for the X-ray studies because its low viscosity allows the substrate to diffuse easily into the crystal. Using a flow-cell they were able to change the mother liquor from 0.01 M sodium acetate to aqueous methanol in a number of stages of increasing concentration and lower temperature until 70% methanol was reached at −55 °C. In these conditions the substrate, N-carbobenzoxy-alanyl-*p*-nitrophenol ester could be added to the cell and its binding followed crystallographically. After equilibrium was attained three-dimensional X-ray data were collected to 3.5 Å resolution. As the original structure determination (Watson, *et al.*, *Nature*, **225**, 806; 1970) was of the tosyl enzyme, Alber, Petsko and Tsernoglou independently determined the structure of the native enzyme at room temperature, and also collected native data at −55 °C. This enabled them to be clear that the enzyme's structure was essentially undisturbed by the transfer from an ionic liquid at room temperature to an organic liquid at low temperature. The difference map calculated from the data sets collected at −55 °C, although not analysed in any detail in accord with the modest resolution limit, was nevertheless fully consistent with the expected productive acyl-enzyme intermediate in the catalytic process as predicted by Fink and Ahmed. The control experiment of raising the temperature of the crystal to −10 °C caused the binding curve to reverse, and the corresponding difference map showed no density remaining in the active site.

It seems certain that this technique will in due course be used to produce

detailed structural information on the acyl-enzyme intermediate, and probably also on other intermediates, of the serine proteinases. This would come close to realising the full potential of X-ray diffraction studies of enzymes, that of being able to obtain a series of "stills" of the enzyme–substrate complex at each point of stability along the reaction pathway, which would indeed be a major contribution to the understanding of enzyme activity, however this understanding may be defined. ☐

Cytoplasmic control of protein synthesis

from Pamela Hamlyn

An EMBO workshop on Cytoplasmic Control of Eukaryotic Protein Synthesis was held on July 19-22, 1976 at King's College, Cambridge and was organised by Tim Hunt and Richard Jackson, Department of Biochemistry, University of Cambridge, and Alan E. Smith, Imperial Cancer Research Fund, London.

FOR many workers in the field of eukaryotic protein synthesis, control of initiation of polypeptide formation is synonymous with translational control. A suitable starting point for the conference was, therefore, to consider the protein initiation factors which regulate the various steps during initiation. Two groups have purified to homogeneity the initiation factors from reticulocytes. W. C. Merrick described the work of the National Institutes of Health group and T. Staehlin that of the Basel Institute for Immunology. Each group has its own system of naming the different initiation factors, but the physical and functional characterisation of the proteins is sufficent to allow them to make correlations with confidence. Four initiation proteins have been isolated from Krebs II ascites cells. H. H. Dahl (ICRF, London) explained their functional activities and described experiments in which reticulocyte factors had been successfully substituted for ascites factors. In the past some initiation factors were claimed to be messenger-specific. Most workers now think that such observations were due to inadequacies in the assay systems used and agree that initiation factors are functionally homologous in different tissues and species.

Tails and caps
Messenger RNAs may have poly(A) tails, 'caps' (blocked and methylated 5' termini) and untranslated sequences either side of the amino acid specifying region. Since these structures may be involved in translational control mechanisms, part of the conference was devoted to them. G. Marbaix (University of Brussels) confirmed that the poly(A) tail confers stability on globin

mRNA injected into oocytes and showed that messenger lacking poly(A) was only degraded once its translation had been initiated. R. Kaempfer (Hebrew University, Jerusalem) showed that globin mRNA requires the 3' non-coding region for its translation but not the poly(A) tail.

The work on the cap region is in an earlier stage, at which many experimental results seem contradictory. In his summary of this group of lectures the chairman, B. P. Perry (Institute for Cancer Research, Philadelphia), concluded that the effects of cap on translation were quantitative and seemed to depend on the messenger, the cell-free system used and the conditions of translation.

Inhibition
The section on the control of initiation centred on the nature of the inhibitor of protein synthesis formed when a reticulocyte lysate is incubated without the addition of haemin. Isolation of the inhibitor results in the co-purification of a phosphorylase activity which can phosphorylate the initiation factor responsible for the formation of the ternary complex between GTP and met-tRNAf. The phosphorylated factor is inactive. Does the phosphorylation cause the inactivation, or is it in some way coincidental? The group from the University of Cambridge have isolated an inhibitor which specifically phosphorylates *de novo* the small subunit of initiation factor IF-E2 (IF-MP). The copurifying kinase and inhibitory activity are heat inactivated at the same rate. Further evidence that phosphorylation of IF-E2 is the inhibitory event is provided by experiments of B. Hardesty (University of Texas) whose group has shown that antibodies to the inhibitory factor, which prevent it acting as an inhibitor, also prevent the phosphorylation of IF-E2. The group from MIT have broadly similar results but are more cautious in their interpretation, pointing out that phosphorylation of IF-E2 may be a normal event at some stage in protein synthesis and that the activation of the inhibitor may alter the normal phosphorylation pattern of IF-E2 and somehow prevent the recycling of the factor. The work

of M. J. Clemens (National Institute for Medical Research, London) indicates that phosphorylation alone is not sufficient to inhibit binding of IF-E2 to the GTP-Met-tRNAf complex. J. A. Traugh (University of California) described phosphorylase activities isolated from a haemin-stimulated reticulocyte lysate. The diagram below illustrates a working model of how she thinks the removal and addition of phosphate to the initiation factor might be involved in the control of polypeptide initiation.
Discussing the action of double-stranded RNA in preventing the translation of encephalomyocarditis virus RNA in an L cell lysate containing interferon, I. M. Kerr (NIMR, London) concluded that there are two steps in the inhibition of translation and hinted that a protein kinase(s) may have a regulatory role in the activation of the inhibitor. In his introduction to the section on interferon and protein synthesis, P. Lengyel (Yale University) pointed out that the effects of interferon were probably many and various. This was borne out by the speakers in this section: no consistent picture of its action emerged.

Developing systems
Some of the best known examples of cytoplasmic control of protein synthesis have been observed in developing systems. mRNA is stored in the cytoplasm and not translated until a further stage in development. Most of the speakers have approached this problem by studying the mRNA before and during its translation to see if there were detectable differences in its properties. C. H. Darnbrough (University of Edinburgh) concluded that, of two populations of messengers with large and small poly(A) size, the latter increased and the former decreased during oogenesis in *Xenopus*. Comparison of the 'active' mRNA isolated from polysomes and the stored RNA from ribonucleoprotein particles, led M. E. Buckingham (Pasteur Institute) to propose that in dividing muscle cells poly(A) tails are involved in maintaining mRNA conformation, rather than

RESULTS obtained by Melton and Giardini (page 309 of this issue of *Nature*) suggesting that oxygen not nitrogen might be the dominant impurity in diamond pose a problem in the light of previous work. In 1936, Robertson *et al.* (*Proc. R. Soc. Lond.,* **A157,** 579–593) classified diamonds into two types by their optical absorption spectra. Kaiser and Bond (*Phys. Rev.,* **115,** 857–863; 1959) using mass spectroscopy, showed that nitrogen impurity was the microscopic basis of this classification; type I diamonds contained nitrogen, type II did not. The nitrogen concentration correlated with the optical absorption lines noted by Robertson *et. al.* Lightowlers and Dean (*Diamond Res.,* 21–25; 1964), using activation analysis, confirmed Kaiser and Bond's results. In some diamonds the nitrogen is paramagnetic, and can be detected unambiguously by spin resonance. Thus there is no doubt that nitrogen is a major impurity in diamond—up to 0.3%—a massive concentration for an impurity in a crystal.

Kaiser and Bond also found small amounts of hydrogen and oxygen. Oxygen has been confirmed by Sellschop (*Diamond Res.,* 35–41; 1975) using activation analysis.

One of the problems in determining the impurity content of diamond is that there are often trapped inclusions of other minerals. These are important, particularly to the geologist, because they indicate the growth environment of the diamond; but they may give a misleading picture of which elements can genuinely enter the diamond lattice as substitutional or interstitial impurities. Kaiser and Bond, and Lightowlers and Dean used stones without visible inclusions. Even so, Sellschop has shown that all diamonds contain submicroscopic inclusions, and these

account for most of the oxygen impurity.

Using mass spectrometry, Melton and Giardini (*Amer. Mineral.,* **59,** 775–782; 1974 and **60,** 413–417; 1975) found that some macroscopic inclusions contain gases—hydrogen, methane, nitrogen, carbon monoxide and water.

Impurities in diamonds

from John Walker

The most abundant element was hydrogen, followed by oxygen and nitrogen. The results are not in conflict with previous studies, because hydrogen cannot be detected by activation analysis, and nitrogen and oxygen need special techniques. The most comparable work is that of Kaiser and Bond, but even here there is no conflict. The latter selected "inclusion-free" diamonds, whereas Melton and Giardini chose crystals containing inclusions, and studied the inclusions.

Thus the picture of impurities in diamond was complicated but consistent. The geologist studies the inclusions; the physicist, the genuine diamond lattice. In particular the physicist, whether he is concerned with optical, electrical, mechanical or thermal properties, knows that type I and type II diamonds have quite different properties, because of their differing nitrogen content.

This consistent picture has been upset by Melton and Giardini's latest paper. They used "inclusion-free" diamonds, and instead of crushing them as previously, they graphitised them at 2,000 °C like Kaiser and Bond. The results are surprising. "The gases released from the diamond, in decreasing

order of abundance, were CO, H_2, H_2O, CO_2, N_2, CH_4, and Ar. The atomic weight percent is O=59.2%, C=28.1%, H=10%, N=2.5% and Ar=0.2%. These data are consistent with the gases released by the crushing of numerous other diamonds *in vacuo*."

Since nitrogen is currently thought to be the dominant impurity in diamond, how can we explain this discrepancy? Melton and Giardini suggest nitrogen contamination from the carbon crucible used by Kaiser and Bond. But this is unlikely because Kaiser and Bond's results are internally consistent—the nitrogen concentration correlated with optical absorption in their crystals. And Lightowlers and Dean, using a different technique, got the same result.

A possible explanation is that the diamonds came from different sources. This is known to affect impurity content. In any case, the fact that Melton and Giardini's diamonds are oxygenrich, surprising though it may be, does not contradict Kaiser and Bond's results on nitrogen. Unfortunately, Melton and Giardini do not give the concentrations of oxygen and nitrogen they found. My estimates based on their data suggest that both lie within the range of accepted values; but it would be better to have the authors' own figures.

One hopes that Melton and Giardini will extend their graphitisation work to diamonds from other sources, and measure the optical spectra before graphitisation, to check Kaiser and Bond's correlations. If the same diamonds could also be studied beforehand by the non-destructive technique of activation analysis, to compare results, the puzzle would probably be resolved. Diamond researchers will await further results with interest.

conferring differential stability. T. Humphreys (University of Hawaii) reported that on fertilisation of sea urchin eggs messenger translation is increased—the messengers are stable but their poly(A) turns over rapidly. Using the same system, G. Giudice (Institute of Comparative Anatomy, Palermo) has shown that although capping does not cause the increase in translational efficiency it may be involved in mRNA selection.

R. A. Laskey (MRC Laboratory of Molecular Biology, Cambridge) has examined the effect on endogenous protein synthesis of injecting polysomes and mRNA into *X. laevis* oocytes. He maintains that oocytes do not have 'extra translational capacity' and that by choosing conditions that accurately reflect the amount of protein synthesised the endogenous protein synthesis decreases competitively with added exogenous mRNA. There is no

competition when the messenger is injected with its own ribosomes. Laskey concludes that the amount of protein synthesised is regulated by a component of normal polysomes and not by messenger availability.

Virus infection
The series of lectures on the control of translation during viral infection was similar to those on masked messengers in development in that many interesting systems were described without providing much insight into the mechanism of control. In general, host mRNA translation is suppressed at the expense of viral protein production. The herpes simplex system was described by C. M. Preston (MRC Virology Unit, Glasgow). He has shown that the effect of this virus on tissue culture cells can be reproduced in a lysate of the cells. The lysate can also respond to exogenous mRNA, but its response is decreased

if the lysate is prepared from infected cells. The lesion can be traced to the ribosomes of the infected cells, since proteins washed off reticulocyte ribosomes by salt treatment restore the translational capacity. R. E. Thach (Washington University) has shown that EMC RNA can 'out-compete' host mRNAs but that the competition is relieved by an excess of the initiation factor corresponding to rabbit IF-E6 (IF-M3). L. Carrasco (ICRF, London) has found that after infection with picornavirus, changes take place in the cell membrane which impair the sodium transport system, leading to an increase in the cell concentration of sodium ions and a decrease in potassium. Experimental evidence has confirmed his suggestion that increased sodium concentration favours the translation of viral, rather than host, mRNAs. It may be that at these altered salt conditions binding of initia-

tion factors to viral messengers is favoured—hence their preferential translation.

In the section dealing with the topography of protein synthesis G. Blobel (Rockefeller University, New York) presented a very appealing model to explain the translation of mRNA for secretory proteins on membrane-bound ribosomes. It requires that mRNAs for secretory proteins code for an N-terminal peptide that is recognised by the membrane, resulting in the attachment of ribosomes to the membrane so that the growing protein is vectorially transported into the intracisternal space. This is illustrated in the diagram : the numbers indicate sequential steps in the synthesis of the protein. Bernard Mechler (University of Cambridge) proposes a slightly different scheme since he has to explain his observation that the binding of ribosomes to the membrane can be mediated by the mRNA directly

rather than its translational product. H. Lodish (MIT, Cambridge) showed that translation of the polycistronic Sindbis virus RNA can take place in the cytoplasm or on membranes using the same ribosomes but producing different proteins. He concludes that the N-terminus of the nascent chain
must specify the binding of ribosomes to membranes.

The participants left the conference with the impression of many examples of cytoplasmic control of protein synthesis but few explanations of the mechanisms involved, an admirable situation sure to keep them in business for several years to come. □

Flow of superfluid ³He

from P. V. E. McClintock

To push some of the newly discovered superfluid ³He through a fine tube, in order to see how it behaved, might seem a particularly obvious experiment, were it not for the daunting difficulties inherent in working at temperatures near 2 mK. In fact, it is a quite remarkable achievement in terms of experimental design and technique that has enabled R. M. Mueller, E. B. Flint and E. D. Adams to report (*Phys. Rev. Lett.*, **36**, 1460; 1976) the first studies of equilibrium flow phenomena, only four years after observation of the superfluid phases was first suspected. Their experiments were carried out in the Physics Department at the University of Florida.

Because of extreme difficulties of making thermal contact in this ultralow temperature range, it is usually necessary to design the cryogenics and the experimental cell as an integral unit. Accordingly, the Florida group have devised an ingenious arrangement whereby a pair of Pomeranchuk cells was used both for cooling the ³He into the superfluid A-phase and also for inducing a flow of liquid through the narrow tube which connected them together.

The Pomeranchuk cooling technique depends on the fact that, at very low temperatures, ³He gets colder if it is solidified by compression. Thus, by applying a mechanical force to reduce the volume of a sample of ³He enclosed in a flexible chamber, thereby solidifying some of it, the remaining liquid may be cooled through the superfluid

transition at 2.6 mK. The mechanical force is usually generated by way of a separate hydraulic system in which the working fluid is liquid ⁴He.

The two Pomeranchuk cells of the Florida apparatus were fitted with completely separate hydraulic systems, so that their volumes could be varied independently of each other. By compressing both cells simultaneously the ³He could be cooled without inducing any movement of liquid in the connecting tube. On the other hand, if one cell was compressed while the other was being expanded, then liquid could be made to flow through the tube at constant temperature. A nuclear magnetic resonance (NMR) technique was used for monitoring events in the flow tube.

In view of a calculation by Fetter (*Phys. Lett.*, **54A**, 63; 1975), it had been anticipated that the flow would result in a shift downwards of the NMR resonant frequency. It was surprising, therefore, that rather than changing its frequency, the resonance line in practice developed satellites, and then abruptly disappeared, as the flow velocity was increased. Although the behaviour was not always reproducible in detail, it was found that the satellite structure never appeared when the external magnetic field was applied at 90° to the flow direction. This may perhaps be related to Fetter's prediction that no frequency shift should be seen in this configuration. A further complication was that, before its final rapid fall, the resonance signal sometimes

diminished in a series of steps as the flow velocity was increased.

The most definite and interesting observation, however, was the remarkably small velocity at which the signal disappeared. The exact value depended on temperature, but fell within the range 0.003–0.02 mm s⁻¹. These velocities are several orders of magnitude smaller than the Landau critical velocity at which the superfluidity would be expected to disappear as a result of pair-breaking, so that some other mechanism must presumably be involved. It is interesting that investigations of the heat conduction by R. T. Johnson, R. L. Kleinberg, R. A. Webb and J. C. Wheatley (*J. Low Temp. Phys.*, **18**, 501; 1975) also yielded multiple critical velocities for the superfluid which were remarkably small (0.2–0.8 mm s⁻¹), although considerably larger than the velocities reported here. The authors demonstrate, however, that the two sets of measurements may in fact be in quantitative agreement if it is assumed that the flow did not occur through a transfer of bulk liquid: if only the superfluid component of the liquid had moved, leaving the normal fluid component clamped in the tube by its own viscosity, it would have had to move relatively briskly to simulate a given rate of apparent bulk flow because it constitutes only a small proportion of the liquid at the temperatures in question. On this basis they deduce superflow critical velocities in the range 0.14–0.64 mm s⁻¹, in good agreement with those derived from the thermal conduction experiments.

Why should these critical velocities be so small? One is immediately reminded of the parallel situation in superfluid ⁴He, where the actual critical velocities for superflow are usually about 1 mm s⁻¹, compared with the much larger Landau critical velocity for roton creation of around 50 m s⁻¹. In the case of ⁴He, the discrepancy has been shown to arise from the relative ease with which quantised vortex lines may be generated in the liquid for flow velocities far below the Landau velocity. It seems very likely that something of a similar nature is happening in ³He. The situation is, of course, infinitely more complicated because the liquid is governed by a vector order parameter, is anisotropic, and takes up complicated textures depending on the shape of the container, applied electric and magnetic fields, and so on. Furthermore, it is not yet by any means clear what would be the analogue of a vortex, in the case of ³He: there may in fact be several different sorts of collective excitation of this general nature.

Assuming, however, that the low critical velocities observed in these experiments arise from the onset of

dissipative processes, it seems probable that at least one completely new type of collective excitation is being created, thus promising to add yet another whole dimension of complexity to our understanding of this extraordinarily complicated liquid. □

Two approaches to gene synthesis

from Maria Szekely

THE recent discovery that synthetic genes can be used to produce genetic recombinants (see *News and Views,* **260,** 189; 1976) opens wide possibilities in the field of genetic engineering. Well-characterised DNA sequences can be inserted into plasmid DNA thus providing specific probes with known sequences for studying the organisation and expression of eukaryotic genomes. Amplification of the inserted gene yields large amounts of specific sequences which can be used for the production or isolation of highly labelled mRNAs, for sequence studies, and so on. At the same time, the safety risk is lessened, as no unknown, harmful genetic information can be integrated into the recombinant.

So far only one eukaryotic gene, that of β-globin, has been inserted into bacterial plasmids. Almost simultaneously, four laboratories reported the production of recombinants from β-globin DNA, using different techniques but all of them starting with reverse transcription of globin mRNA into cDNA. (Rougeon *et al., Nucleic Acids Res.,* **2,** 2365, 1975; Efstratiadis *et al., Cell,* **7,** 279, 1976; Rabbits, *Nature,* **260,** 221, 1976; Higuchi *et al., Abstract ICN-UCLA Winter Conference,* 1976). The advantages of this technique are obvious, there are, however, also some limitations to the method. It follows from the principle of the technique that the DNA inserted into the plasmid can contain only the sequences present in the mRNA : any additional, non-transcribed sequences that may be present in the original gene will be lost. It remains to be seen how their absence affects the function of the integrated gene. In practice, the limitations go even a step further : it depends on the efficiency of the reverse transcriptase how much of the genetic information present in the mRNA will be passed on to the synthetic gene. In many laboratories only fragments of cDNA copies could be obtained with this enzyme. Rougeon *et al.* used a 300–400 nucleotide long cDNA preparation to synthesise the double-stranded globin DNA and after amplification ended up with a 100 to 150

base-pair long integrated globin DNA, about one fifth of the length of the mRNA.

Maniatis' group reported last year the synthesis of a full-length copy of globin mRNA (Efstratiadis *et al., Cell,* **4,** 367; 1975). A few months ago the same group described the sythesis of double-stranded globin DNA with the aid of DNA polymerase I, making use of the hairpin loop structure at the 3′-end of this cDNA, which served as primer in the synthesis of the anti-cDNA strand. (Efstratiadis *et al., Cell,* **7,** 279; 1976). They succeeded in inserting this synthetic gene into PMB 9 plasmid DNA and in their recent paper (Maniatis, Kee, Efstratiadis and Kafatos, *Cell,* **8,** 163; 1976) they describe in detail the techniques of integration of the DNA, transformation of *Escherichia coli* cells and identification of the recombinant.

The synthetic gene is 580 base pairs long, about 80 nucleotides shorter than β-globin mRNA. It contains the full coding region plus 40 and 110 nucleotides of the untranslated regions at the 5′ and 3′ termini, respectively. Molecular hybrids were constructed by annealing the globin DNA which carried poly(dT) tails to *Eco*RI-treated plasmid DNA to which poly(dA) tails have been attached. Transformation of *E. coli* HB101 with this hybrid DNA yielded 600 tetracycline-resistant colonies, a high proportion of which contained sequences of the β-globin gene, as was shown in hybridisation assays. The size of the inserted DNA did not change upon construction of the molecular hybrid, transformation and cloning.

The method seems suitable for general application in the synthesis and amplification of eukaryotic genes. Maniatis' group has already synthesised a number of other genes by copying eukaryotic mRNAs.

It is essential for the usefulness of such techniques that the original structure of the gene should be retained in the recombinant. Fidelity in copying the mRNA and stability of the DNA structure during integration and transformation is therefore of vital importance. Maniatis *et al.* characterised the synthetic gene and the inserted globin DNA after amplification by comparing restriction maps of the DNAs and correlating them to the structure of globin mRNA. Using eight restriction enzymes with known recognition sequences, the restriction map of synthetic DNA was established and compared with the cleavage pattern predicted from the nucleotide sequence of β-globin mRNA. As only part of the nucleotide sequence has been determined so far, some cleavage sites were established by deducing the nucleotide sequence from the known amino acid sequence of β-

globin. The restriction map of synthetic globin DNA was in perfect agreement with that expected from the mRNA structure.

The same restriction enzymes were used individually and in combination on the recombinant DNA. By using *Hha* endonuclease, an enzyme which does not cleave synthetic globin DNA but produces many fragments from PMB 9 DNA, one fragment, carrying the inserted globin gene could be isolated and characterised. The restriction map of this fragment was established, and the orientation of the inserted DNA and the distance between the restriction sites determined. These proved to be the same as in the synthetic gene before integration, confirming that the entire synthetic globin DNA molecule was amplified without sequence rearrangements. Some slight changes were detected in the poly(dA)-poly(dT) tails only.

The approach used by Maniatis' group yields very useful DNA probes which will greatly enhance progress in our understanding of the structure and function of the eukaryotic genome. The success of a different, more chemical approach has been reported recently from Khorana's laboratory : the complete gene of suppressor tyrosine tRNA of *E. coli* has been synthesised without using an RNA template. The techniques were worked out years ago by Khorana's group. Following a known nucleotide sequence, chemical synthesis is used to produce blocks of nucleotides and the ligase reaction to join them. The synthetic gene contains the total sequence of the precursor tRNA and includes the sequence of the promoter site and of the stop signal for transcription. Twenty-four scientists contributed to its synthesis which has taken 9 years. This gene has now been introduced into an *E. coli* amber mutant by way of a transducing phage (the details of the technique have not been published so far) and it was found to function correctly as a suppressor gene in the bacterial cell.

Khorana's method requires more time and work than the copying of an RNA template and its use is limited to the synthesis of genes the sequence of which has been fully established. Still, this approach has some great advantages over the reverse transcription of RNAs. The gene synthesised by Khorana contains also sequences which are not present in the final gene product, sequences lost during processing of the RNA and non-transcribed control signals. Such sequences cannot be incorporated into a reverse transcript. The purely synthetic method also makes it possible to introduce specific alterations into the gene structure and to study the effect of such "mutations". It would be interesting to

see if the two approaches could be combined and a new technique developed which would unite the relative simplicity of the copying technique with the further possibilities provided by the methods of chemical synthesis. □

New method for measuring nuclear lifetimes

from P. E. Hodgson

AN ingenious method for measuring very short nuclear lifetimes has recently been developed that greatly extends the range covered by existing techniques. This is an important advance because these lifetimes can often be calculated from nuclear wavefunctions, and thus provide a sensitive test of the theories used to calculate the wavefunctions.

Nuclear lifetimes are usually measured by the delayed coincidence and the Doppler shift techniques, and these cover a wide range of times greater than about 10^{-15} s. For shorter lifetimes there has hitherto been only the blocking technique which is restricted to a few suitable materials. The new method seems likely to provide a way of measuring lifetimes from about 2×10^{-15} to 6×10^{-18} s, and thus extends the region of measurable lifetimes by more than two orders of magnitude.

The new method is based on a very simple idea. If a nucleus of charge Z decays by electron capture to an excited state of another nucleus of charge $(Z-1)$ a vacancy is left in the atomic K-shell from which the electron has been captured. This vacancy will soon be filled by a transition from a higher atomic state with the emission

Histogram showing the spectrum of all X rays in coincidence with all decay protons. The curves show the spectra measured independently for the As and Ge decays.

of an X ray. Now if the X-ray transition takes place before the nuclear state decays, its frequency is characteristic of the nucleus of charge $(Z-1)$. But if the nucleus decays by proton emission before the X-ray transition takes place, then the X ray will have a frequency characteristic of the nucleus of charge $(Z-2)$. Since these X-ray frequencies can easily be measured, it is easy to find out whether the nuclear decay took place before or after the atomic decay. In practice there is of course a distribution of decay times for both processes, so it is the relative proportion of the two types of decays that is measured and this gives the ratio of the nuclear and atomic lifetimes. Since the atomic lifetimes are well known both experimentally and theoretically, the nuclear lifetime is found.

This method has been devised by a group of scientists from the Chalk River Laboratories and the University of Toronto in Canada. They have obtained data on the lifetimes of ⁶⁵Ga, ⁶⁹As, ⁷³Br, and ⁷⁷Rb, and in their first publication (*Phys. Rev. Lett.*, **37**, 133; 1976) they give details of their result for ⁶⁹As.

In this case the decay sequence starts with $^{69}_{34}$Se undergoing electron capture to an excited state of $^{69}_{33}$As, which in turn undergoes proton emission to a state of $^{68}_{32}$Ge.

The initial nucleus ⁶⁹Se was produced in the ⁴⁰Ca(³²S,2pn)⁶⁹Se reaction using the 100 MeV beam of the Chalk River tandem Van de Graaff accelerator. After irradiation, the target was moved rapidly to a counting position where arrays of counters measured the X rays from the atomic transitions, the delayed protons from the decay of the ⁶⁹As to ⁶⁸Ge, and the gamma rays from the nuclear transitions in As.

The histogram in the figure shows the energy spectrum of all the X rays in coincidence with the delayed protons, compared with normalised curves corresponding to the decays of Ge and As found in independent measurements. It is clear that the histogram can be very well fitted by the sum of these two curves.

Many states of ⁶⁹As can be reached by electron capture, so the decay protons are themselves varying in energy. Since the relation between the relative numbers of Ge and As X rays depends on the proton energy, so do the lifetimes of the states of As. The lifetimes of the states in As vary from 2×10^{-16} to 10×10^{-16} s. These numbers are average lifetimes for successive bands of states and rather detailed calculations based on the statistical theory of nuclei are required to interpret them in detail.

If there had been only one state in As fed by the electron capture in Se the experiment would have given an

unambiguous determination of its lifetime. The technique is clearly successful and is likely to be applied to determine the lifetimes of many states, and hence to increase our knowledge of nuclear structure. □

Effects of a long hot summer

from Peter D. Moore

THE unusually warm and dry summer experienced in Britain this year has undoubtedly influenced our vegetative cover. Apart from widespread damage by fire, the high temperatures and low water availability have themselves produced some very evident changes. Roadside verges and lawns are parched, with only the deep-rooted rosette species showing signs of life. Among trees, birch appears particularly susceptible and dead birches are now abundant on heathlands and in mixed woodland both in the lowland and the upland zones of the country.

Many of the common species affected will probably recover quickly and even if they do not, any change in status will be difficult, if not impossible, to assess. There are certain species, however, which may merit especial attention at this time, such as those which lie at their climatic limit in Britain and which may expand or contract their range as a result of the effects of this and preceeding summers. There are also those species which are restricted to lower altitudes in the British Isles because of the shorter growing season in higher regions; they may attain new heights. And there are those arctic alpine species which are limited by high summer temperatures and which may, therefore, be suffering.

One species which reaches its northwestern limit of distribution in the British Isles and which might be expected to respond to the present conditions is the stemless thistle (*Cirsium acaulon*). Pigott (in *The Flora of a Changing Britain*, edit. by Perring, F., 32, Classey, Hampton, Middlesex, 1970) has shown that the temperature of the flowering head of this plant is critical in determining the rate of development of the embryo. Only in southern and eastern Britain does the plant normally produce viable seed, though some outlying populations in the north and west appear to have been established during exceptionally warm summers.

Many plants are common at fairly low altitudes and yet fail to flourish on mountain summits because of their inability to grow adequately, or flower, or produce mature, viable seed, within
NEW observations of H-β or Lyman-α fluxes of a sample of 57 Seyfert galaxies and QSOs suggest strongly that QSOs are indeed distant, bright Seyfert galaxies too remote for the faint outer structure of the galaxies to be observed. As well as confirming the now increasingly accepted view that the redshifts of QSOs are cosmological distance indicators, the suggestion that QSOs are high-redshift Seyferts provides a new use of these objects as cosmological probes, and suggests some limits on the so-called "deceleration parameter" of our Universe.

The possibility of a link between active galaxies such as Seyferts and QSOs has long been recognised in a qualitative sense, two touted possibilities being that explosions on the scale of a QSO may occur in the nuclei of all spiral galaxies from time to time, or that such violent activity may mark a step in the evolution of a proto-galaxy, after which it settles down into a quiet spiral with no further comparable activity. Supporters of such ideas have had powerful circumstantial evidence to hand in the observation that class I Seyferts and QSOs cannot be distinguished from their spectra alone. Both have broad Balmer emission lines, narrow forbidden lines and power-law spectra, the difference being that Seyferts are seen as active nuclei surrounded by visible galactic material, while QSOs have higher redshifts and no surrounding galaxies are seen. Because of the confusion effects from bright nuclei, surrounding galactic disks could not, however, be observed at redshift greater than 0.1—so any Seyfert of class I with $z>0.1$ would be identified automatically as a QSO.

Weedman has now developed from this observation a quantitative

Seyfert galaxies and QSOs

from John Gribbin

measure of the similarity between the two kinds of object (*Astrophys. J.*, **208**, 30–36; 1976). Earlier studies along these lines had compared the fluxes from the two in a specified part of the observed spectrum; as Weedman points out, this is not the best approach because the redshift effect means that different parts of the emitted spectra are shifted into the chosen observational window. Instead, he has made measurements of the emission of his sample of Seyferts and QSOs in the hydrogen lines, H-β or Lyman-α. The H-β lines were measured wherever possible, but at large redshift these are shifted out of the visible range and for those objects L-α can be measured instead, the relative strength of the two lines (based on model calculations by K. Davidson, *Astrophys. J.*, **171**, 213; 1972) then giving an estimate of the strength of the invisible H-β.

The results show clearly a continuous smooth distribution of luminosity in line with the cosmological interpretation of the redshifts of these objects. The range covered, equivalent to 11.5 magnitudes, is large, but as Weedman points out still less than the luminosity range of main sequence stars. Accepting this as confirmation that QSOs are simply bright class I Seyferts, this immediately provides a new probe of the Universe extending over a wide range of redshifts, and Weedman points out some preliminary conclusions from this which set limits on some cosmological parameters. In particular, the luminosities of high redshift QSOs (which are now regarded as high-redshift Seyferts) are relatively faint, suggesting that either there is some limit to the brightness of these objects or that the deceleration parameter of the Universe, q_0, is negative. This tentative first conclusion is, however, less important than the fact that at last it seems possible that QSOs can be used with confidence as genuine cosmological probes to define the structure of our Universe on the large scale, and to rule out some of the large family of possible models now applied to the Universe. The problem of the energy source of QSOs remains, of course (even if there is some upper limit), but here too it seems that this problem can now be approached from a new and promising direction by investigating the more easily studied and nearer members of the family, the Seyfert galaxies.

---

a short growing season. Pearsall (*Mountains and Moorlands*, 49, Collins, 1956) described his observations on the heath rush (*Juncus squarrosus*) and showed how the length of the flowering stalk, the number of flowers per inflorescence and the number of viable seeds produced per capsule are all inversely related to altitude. The production of viable seed for this species is uncommon at altitudes over 820 m. It is also reported, however, that the heath rush produced seed on the summit of Ben Wyvis (1,036 m) in the unusually warm summer of 1947.

Among lowland plants, some occur only in those parts of the country experiencing high summer temperatures. For example, the round-headed rampion (*Phyteuma tenerum*) occurs mainly within the 16.6 °C July average isotherm. Such species may also be expected to extend their range under current conditions.

Other species may find high summer temperatures detrimental, particularly species of arctic alpine distribution. Dahl (*Oikos*, 3, 22; 1951) observed that

arctic alpine species grown in lowland gardens suffered most during hot summers. He has also demonstrated that many of these species have distributional patterns in which their limits coincide with low summer temperatures. Similar observations have been made recently for certain arctic alpines in Newfoundland (Damman, *Can. J. Bot.*, 54, 1561; 1976), for example, the bog bilberry (*Vaccinium uliginosum*) is found only in areas having an average temperature in the growing season below 15 °C. It is known that dark respiration rates of many arctic alpine species are higher than their lowland counterparts (Billings and Mooney, *Biol. Rev.*, 43, 481; 1968) and since respiration is stimulated by high temperatures, the plant could experience difficulty in maintaining a positive carbon balance during a hot summer.

One species which does appear to be suffering in upland Britain this year is the bilberry (*Vaccinium myrtillus*). This is a species which dominates some open moorlands in the uplands of western Britain, yet is found only under a

woodland canopy in the east and in continental Europe. Microclimatic factors, possibly involving temperature and humidity may therefore be critical for its survival. This summer the open populations of the west are showing evident signs of stress when unprotected by a tree cover. It is possible that its reduced vigour will allow such species as the heather (*Calluna vulgaris*) to spread at its expense.

Our freak summer offers valuable opportunities to increase our understanding of many plant species and one can only hope that any ensuing changes in vegetation will not remain unrecorded. This may be an appropriate time to mobilise that large and willing labour force, the amateur botanists, to undertake a census of selected plant species on the model of the British Trust for Ornithology's common bird census. Perhaps the Botanical Society of the British Isles is the appropriate organisation to initiate such a census which could begin to provide an answer to the question how responsive and fluid is our flora? □

Structure and function of haemocyanin

from J. V. Bannister and H. A. O. Hill

The V Haemocyanin Workshop sponsored by the European Molecular Biology Organisation was held on August 1–4, 1976, at the new Marine Biology Laboratory of the University of Malta. The meeting was organised by the Department of Physiology and Biochemistry of the University.

THE haemocyanins are multisubunit copper proteins with respiratory function found in arthropods and molluscs. The molecules are of giant size with a molecular weight of up to 1 million in arthropods, 4.5 million in cephalopods and 9 million in gastropods. The stoichiometry of oxygen binding is one O_2 per two Cu and the copper content indicates a minimum functional subunit of 75,000 in arthropod and 50,000 in molluscan haemocyanin. Subunits of 75,000 molecular weight appear to exist in arthropod haemocyanin and can be regarded as monomers. The monomer molecular weight in molluscan haemocyanin has not been fully resolved.

The study of the structure and behaviour of these extra-large molecules is a matter of real importance, providing as it does a stepping stone to the understanding of the regulation and assembly of still larger biological structures, such as microtubules or ribosomes (J. Wyman, University of Rome). Three-dimensional image reconstruction from electron micrographs has provided a model for gastropod haemocyanins (Mellema and Klug, *Nature*, **239**, 146; 1972) which showed the molecule to consist of a hollow cylindrical drum closed at both ends with material of fivefold symmetry ("collar") containing a "cap" in the centre. The wall has approximately tenfold rotational symmetry and consists of 60 quasi-equivalent morphological units bounded by two dominant sets of helical grooves. E. F. J. Van Bruggen (University of Groningen) presented results on the possible folding of a long polypeptide chain in the strongly curved wall segments from a half molecule. A segment would accommodate one-twentieth of the molecule of *Helix pomatia* haemocyanin and one-fifth of the fivefold "collar". The "cap" of Mellema and Klug is thought to be an artefact. It has proved difficult to dissociate gastropod haemocyanins into material smaller than one-twentieth of the molecule (about 450,000 molecular weight) without breakage of peptide bonds. The twentieths have therefore been regarded as the monomers of these haemocyanins. If so a monomer contains about nine oxygen binding sites or "domains". C. Gielens (University of Leuven) showed that two sites between the domains are susceptible to proteolysis. Various proteolytic enzymes including subtilisin, papain and Pronase give 50,000 molecular weight fragments with whelk, *Murex trunculus* haemocyanin (J. Bannister, University of Malta). Similar fragments were observed after prolonged reduction followed by carboxymethylation of the haemocyanin. The protomer may therefore be as small as a single O_2 binding domain in this haemocyanin.

The structure of arthropod haemocyanins seem less perplexing. The assembly of 60S molecules in *Limulus*, and 34S in scorpion and tarantula haemocyanins, from 16S subunits was discussed (E. F. J. Van Bruggen, University of Groningen; J. Lamy, University of Tours; B. Linzen and R. Loewe, University of Munich). Each 16S particle contains six monomers (5S). B. Salvato (University of Padova) questioned this structure of the 16S subunit in *Limulus* haemocyanin. W. Love (John Hopkins University) reported the conditions in which whole molecules of *Limulus* haemocyanin and some of its subunits can be crystallised. The crystal forms from which preliminary X-ray data were obtained are still unsuitable for high resolution structure analysis and conditions are being sought for the growth of more suitable crystals. The 60S whole molecule is predicted by X-ray diffraction to consist of about 50 subunits of which there are at least nine different kinds present in unknown ratio.

Limulus haemocyanin can be dissociated into five distinct subunits (I–V) of about 66,000 molecular weight. The fully associated molecule is therefore a 48-meric structure. Van Bruggen discussed the association of subunits I–V as seen in electron micrographs. The 5S structure is a roughly spherical protein particle with a diameter of about 65 Å. None of the separated subunit fractions was found to be capable of forming an intact 60S structure by itself. The 60S structure is formed by the stacking of two-bridged tetramers probably in a staggered arrangement. The heterogeneity of the 5S subunits was demonstrated in scorpion haemocyanin by Lamy. Six subunits could be isolated from the haemocyanin, one of which—subunit 4—was shown to have a particular ability to polymerise in one, probably hexameric 16S particle.

Until now the O_2 bound in haemocyanin has been considered to form a peroxo complex with two Cu(II) atoms. R. Lontie (Leuven) proposed consideration of a Cu(I) . . . Cu(III) complex. X-ray photoelectron spectroscopy, however, indicates that Cu in oxy-haemocyanin is cupric because the $2p_{3/2}$ and $3p_{3/2}$ binding energies of the Cu are similar to those in Cu–Zn superoxide dismutase (H. Van der Deen, Groningen).

Oxyhaemocyanins have a strong absorption band in the near ultraviolet. Photo-oxidation experiments with light at the absorption wavelength show that tryptophan is located near the copper-oxygen site (G. Jori, Padova). M. De Ley (Leuven) proposed that photo-oxidation of haemocyanin results in the activation of oxygen by tryptophan.

Haemocyanins show both a reverse and a normal Bohr effect. Cooperativity is observed with whole or half molecules and is mediated by divalent ions or high ionic strength. The O_2 equilibrium and kinetics of gastropod and arthropod haemocyanins were discussed. Undissociated *Panulirus interruptus* haemocyanin under conditions of co-operative O_2 binding was reported to show a non-autocatalytic oxygen dissociation behaviour (H. Kuiper, Groningen). Temperature-jump studies showed that the oxygenation reaction is heterogeneous in *Limulus* haemocyanin and its isolated subunits (C. Bonaventura, Duke University Marine Laboratory). The reverse Bohr effect in *Buccinum* haemocyanin was investigated by E. Wood (University of Leeds). The kinetic explanation for this effect was reported to be that the dissociation velocity constant was strongly *p*H-dependent whereas the association explanation was reported for a positive Bohr effect except that the *p*H dependency of the velocity constants goes in the reverse direction (M. Brunori, University of Rome).

The question of whether molluscan and arthropod haemocyanins are similar because of convergence or are homologous and have descended from a common ancestral gene remains unanswered. A. Ghiretti-Magaldi (Padova) showed that the available amino acid compositions of several arthropod and molluscan haemocyanins can be used to reconstruct a consistent evolutionary tree.

Since the first Haemocyanin Workshop in Naples 10 years ago, much progress has been achieved but nevertheless, the protein is proving to be more difficult to study than was first imagined. ☐

Cyclic climatic variations in climate over the past 5,500 yr reflected in raised bogs

Bent Aaby

Geological Survey of Denmark, Thoravej 31, DK-2400 Copenhagen NV, Denmark

Investigations of Danish raised bogs apparently indicate cyclic long term climatic variations with a periodicity of about 260 yr over the past 5,500 yr. The result could be used for modelling future climatic trends.

RAISED bogs represent a special type of peat bog. they are lens shaped, and highest in the centre. They receive no minerogenic water from their surroundings, but have their own water regime, with all of the moisture supplied from the atmosphere, as rain or snow. The humidity in the upper peat layers depends, therefore, essentially on precipitation, temperature and evaporation, a fact which makes raised bogs very sensitive to variations in climate.

Though past climatic changes are reflected in raised bogs as variations in the degree of decomposition (or humification) of the peat, interpretations are not straightforward. For example, a trend towards accumulation of more light coloured peat (decreasing humification) indicates increasing humidity in the bog, which may be attributable either to higher precipitation or lower temperature, or to a combination of the two. It is not possible to identify which of the two parameters is responsible, or to tell exactly how drastic or persistant a recorded climatic change may have been. The opposite shift, from light to dark coloured peat, does not necessarily depend only on climatic parameters, because peat formed under stable climatic conditions will also show the same trend in decompositional behaviour, since the increase in the relative distance to the water table changes as new peat accumulates. Shifts to drier bog conditions are therefore ignored as indicators of climatic changes.

Although changes from dark to light peat formation may indicate climatic shifts, local conditions, such as surface drainage patterns, may also affect patterns of peat formation. It is therefore important to investigate large open peat sections to distinguish widespread alterations (to be found at three or more places in a section) from local alterations. The surface of raised bogs from suboceanic areas comprises drier hummocks and wetter hollows. General variations in the water regime often cause an alteration in their distribution pattern (Fig. 1).

From the rather stationary centre the hummocks transgress in stable and/or dry periods and regress when conditions become generally wetter. A theoretical section, based on the Draved bog profile is shown in Fig. 1B. It can be demonstrated that Draved hummocks have existed at the same place for more than 2,500 yr, contrary to the theory of cyclical hollows/hummock succession (see, for example, ref. 1). Accordingly, an autonome succession between hollows and hummocks cannot have been responsible for the observed shifts in peat formation.

The hollow peat is more likely to reveal a detailed record

than the hummocks, where smaller variations in the humidity are not registered. Levels corresponding to the transgression and regression stages of the hummocks can be detected by measuring humification variations in the hollows.

Obtaining the material

I investigated a number of large, open peat sections in five raised bogs in Denmark. All of the bogs cover a rather extended area (more than 200 ha), and the sections are situated in the central part of the bogs. The degree of humification was measured by the colorimetric determination (see ref. 2). A humification curve is shown in Fig. 2, together with the relative frequency of two rhizopod genera. These genera occur in raised bogs connected to the moist part of the bog surface. Population frequencies reinforce indications of past changes in the water regime on the bog, as reflected in the humification curve.

Levels reflecting past climatic changes have been dated using the radiocarbon method. From Draved Mose a time/depth scale[2] based on 55 radiocarbon dates has been used. In the other cases one or two samples above and beneath levels in question have been dated. The ^{14}C dates have further been calibrated to calendar years in accordance with the American bristlecone pine chronology (see ref. 3).

Figure 3 shows the dates of climatic shifts as determined in Danish bogs. Some dates are identical within statistical uncertainty, reflecting the general character of the climatic events. For example, the onset of colder and/or more humid weather conditions around AD 500 has been recognised in four different bogs[4]. The dates seem to be systematically distributed in time. Generally, there is a time interval of around 260 yr between palaeoclimatic shifts, as indicated in the left-hand side of the figure; but sometimes there is the double time span, 520 yr, between shifts. The reason could be that the intermediate climatic changes were too weak to be reflected in the bogs (for example, the missing shift around AD 1800, see Fig. 4), or that data are too sparse to show missing events. A few dates seem not to accord with the supposed periodicity (at ~ 1400 BC and ~ 2000 BC).

Although the raised bogs do reflect past climate, not every climatic shift is indicated in the peat structure because the rate of decay is rather slow. The degree of decomposition may therefore rather depend on general environmental conditions during an extended period[5]. When light, weakly decomposed peat was formed, wet periods were more frequent than dry ones, while opposite conditions prevailed when dark peat formation predominated. Raised bogs are therefore supposed to react as biological low pass filters only reflecting general long term tendencies
Fig. 1 *A*, Part of a 30-m long peat section from the central part of Draved Mose. The bog lies on aeolian sand. Peat formation began about 5500 BC. *a*, Slightly humified, sphagnum–vaginatum peat; *b*, moderately humified sphagnum–vaginum peat; *c*, highly humified sphagnum–vaginum peat; *d*, disturbed peat layer; *e*, hydromor; *f*, sand; *g*, charcoal layer; *s*, sampling sites. Top, visual variations in peat colour, together with distinct charred layers. Highly humified peat (*c*) dominates most of the section at about 1,873.5 m (at sampling site S₂) and at 1,879.0 m, where two hummocks have existed for more than 2,500 yr. From the rather stable centre the hummocks transgress in dry periods and regress when it becomes generally wetter (see *B*). Bottom, Approximately synchronous levels. Based on the three distinct charred layers (two lying close together at 16.90–16.95 m and one at 17.60 m) and 55 radiocarbon dates from sampling site S₁, the bog development in this area has been reconstructed. General changes from dark to light peat formation occur nine times (see the symbols). The dates of changes are given rounded off to
the nearest 50 yr. *B*, Theoretical peat section, showing that the hummock area increases in dry periods, and becomes smaller in wetter periods.

in climate, and the 260-yr cycle seems to be the shortest periodicity revealed.

This interpretation of changes in the degree of humification is supported by historical evidence from the past millennium. From England a temperature curve for the past 1,100 yr is available (Fig. 4). If the curve is smoothed by a 200-yr low pass filter it shows the same general climatic trend reflected in the Danish bogs. The latest period of colder/wetter climate previously detected from raised bogs occurred during the first part of the sixteenth century, that is, at the beginning of a temperature decline corresponding to the onset of the "little ice age". The preceding change in peat formation patterns (in the middle of the thirteenth

century) seems to correspond to the end of the mediaeval warm periods. The English temperature curve before AD 1100 is rather uncertain (H. H. Lamb, personal communication) and cannot be used for control purposes. Ice-isotope investigations, however, indicate that colder conditions prevailed around AD 1000, as do the Danish bogs. Younger variations from dark to light peat formation thus apparently reflect climatic changes and the same is probably true for older peat variations. Figure 4 also shows that there may be little (probably less than 50 yr) or no time lag between dated humification changes and the beginning of long term climatic trends.

Following the most recent humification change during
Fig. 2 Degree of humification and content of two rhizopod genera in a vertical peat column in hollow peat from Draved Mose (S₁, Fig. 1). Arrows, Levels assumed to reflect climatic shifts.

Fig. 3 Record of climatically conditioned shifts from dark to light peat formation, derived from sections in 5 Danish raised bogs. Dotted lines, dates of changes reflected in Draved Mose; full lines, results from other bogs.

the first part of the sixteenth century, another change should have occurred during part of the eighteenth century. It may indeed be noticed that a decrease in temperature occurred at that time on the England temperature curve (Fig. 4). That cooling trend was distinctly weaker than preceding ones in the thirteenth and sixteenth centuries, and was perhaps too small to leave traces in the Danish bogs.

Statistical calculations

A statistical test was made to check the significance of the apparent periodicity of humification patterns, and also to determine more accurately the length of the period.

Groups of dates in Fig. 3 differing by less than the statistical uncertainty of the datings have been considered as reflecting the same climatic events, dated to an arithmetic mean. This procedure reduces the number of events under consideration from 39 to 17, each having a smaller statistical dating uncertainty than if the dates were considered independently.

Series of dates were established with constant time intervals $T=250$, 260 and 270 yr, respectively. For each value of T the phase of the series was chosen so as to minimise the deviation of the observed dates of events from the expected dates; for example, AD 1520 was used as the youngest date in the series $T=260$ yr. It was assessed

Table 1 Distribution tests of dates indicating climatic changes (see Figs 3 and 5*b*) from three cyclic periods*

	250 yr	260 yr	270 yr
Uniform distribution test	Accepted	Refused	Moderately accepted
Significance level	20%	≪1%	9%
Normal distribution test		Accepted	Moderately accepted
Significance level		77%	5%
Minimised standard deviation		±41 yr	±74 yr

* Dates lying close together in time are supposed to reflect the same variation in climate and are only taken as a single event, dated to the arithmetic mean of the dates, which minimises standard deviations.

whether the deviations from the three periods were uniformly distributed over the entire interval. Table 1 shows that this seems to be the case for $T=250$ years, indicating no periodicity of that length.

The deviations in the two other series may show a systematic variation, and the probability that they are normally distributed has been tested (Table 1). Both the normal distribution test and the standard deviation test identify $T=260$ yr as a significant periodicity in the original series of events (Fig. 5). The standard deviations on the calibrated radiocarbon dates were not included in the calculations, but it seems likely that the calculated standard deviation in Table 1 is of the same order as, or slightly smaller than, the standard deviation of the individual calendar dates. This may indicate that in most cases the standard deviation is attributable to the uncertainty in the dating method. I thus propose that a major long term fluctuation in climate has had a rather distinct cyclicity with a periodicity of about 260 yr during the past 5,500 yr in north-western Europe.

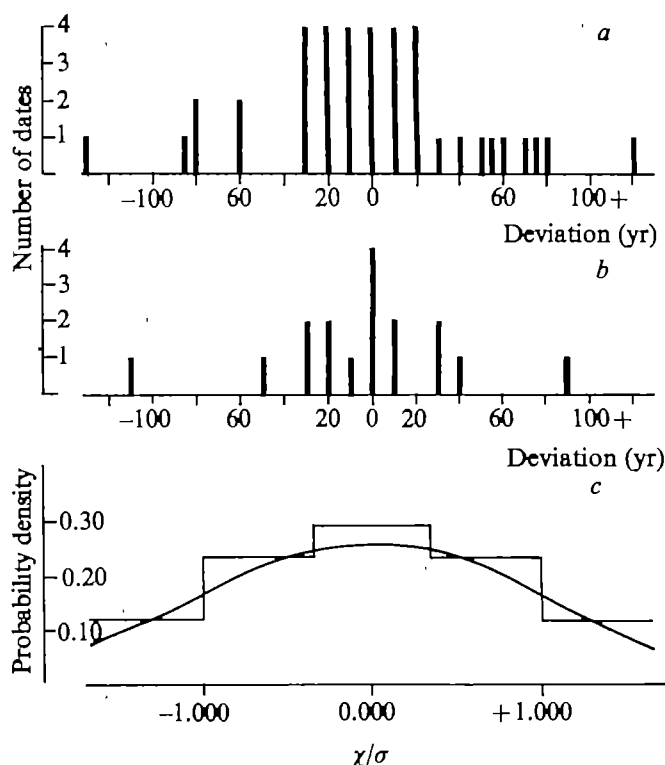
Fig. 4 Relationship between long term trend of temperatures in central England, shown as 50-yr means, and dates of climatic shifts indicated by bog investigations (full lines). Temperature curve based on instrumental observations back to AD 1700, and before that time on historical records; the oldest part is rather uncertain (H. H. Lamb, personal communication). The curve has been smoothed by a 200-yr low pass digital filter (see refs 5 and 6). An expected change in peat formation around AD 1780 was not found in the bog profiles and is shown as a dotted line.


Fig. 5 *a*, Deviation (yr) from a climatic periodicity of 260 yr, beginning in AD 1520 (see Fig. 3). *b*, The same calculations based on the assumption that shifts dated to almost the same time (using ^{14}C analysis) are strictly synchronous and dated to the mean of the dates. *c*, The actual distribution of the 17 deviation dates from *b* compared with the normal distribution curve having the same mean and variance.

Future climate

To demonstrate periodicity, a time span of generally more than 10 times the length of the individual periods concerned must be considered. In this investigation the time interval has been extended to about 5,500 yr, or more than 20 times the length of the period in question. It is therefore justifiable to use the observed periodicity to predict future climatic trends. This suggests that a general trend towards decreasing mean temperatures and/or wetter conditions may begin in the last part of this century or in the first part of the twenty-first century in north-western Europe.

Predictions of long term trends in climate have previously been based on ice-isotope[7] and tree-ring[8,9] data from the past millennium, and even though these predictions essentially agree, caution must be applied in interpretation particularly as a physical explanation for climatic changes is still lacking. Pollution of the atmosphere may turn out to be a dominating factor in the future[10]. Perhaps resulting in climatic trends different from projected natural trends.

On the other hand, the Danish bog data could contribute to the design of an atmospheric model sufficiently reliable to provide some hints as to the future trends.

Complementary base pairing and the origin of substitution mutations

Michael D. Topal & Jacques R. Fresco

Department of Biochemical Sciences, Princeton University, Princeton, New Jersey 08540

On the basis of chemical considerations and model building, the Watson–Crick concept of complementary base pairing is extended to a wider range of DNA pairs than A–T and G–C (including A–C, G–T, A–A, G–G and G–A) by invoking imino or enol tautomers (or protonated species) and syn isomers. The virtual absence of these additional base pairs from DNA is explained in terms of the low frequency with which these unfavoured forms occur and the two-step mechanism of DNA synthesis, whereby residues are first incorporated by the DNA polymerase and then checked. This base-pairing hypothesis is used to explain the origin, nature and level of spontaneous substitution mutations, their enhancement by base analogues, and the unique effects of certain mutator alleles.

ALTHOUGH the bi-helical complementary base-paired structure of DNA implies mispairing events as the principal means for generating substitution mutations, a general mechanism for mispairing has not emerged. Watson and Crick did suggest as part of their formulation of replication that spontaneous mutations might be due to the occasional occurrence of a pu–pyr pair with a base in one of its less likely tautomeric forms[1]. But while plausible, this suggestion fails to explain the observed frequencies of spontaneous substitution mutations, 10^{-9} to 10^{-12} per base pair synthesised[2], simply from the estimated frequencies of unfavoured tautomers in solution, 10^{-4} to 10^{-5} (refs 3–6). Moreover, while pu–pyr mispairing events involving minor base tautomers have been conceived as a qualitative rationale for the origin of transitions, a comparable set of mispairs leading to transversions has not been proposed. A mispairing rationale for the mechanism of many chemical mutagens is also wanting.

We describe here a general base-pairing hypothesis that explains both qualitative and quantitative features of substitution mutations. This hypothesis is based on well recognised chemical features and isomeric equilibria of nucleotides and the notion that the expression of these equilibria accounts for the level at which mispairing events occur. The hypothesis depends on two principal assumptions. The first is that there is a wider set of complementary base pairs than the two proposed by Watson and Crick[7], A–T and G–C, that are compatible with the steric constraints of a regular DNA helix (Fig. 1). The non-Watson–Crick complementary pairs constitute mispairs of two types, pu–pyr, which can give rise to transitions, and pu–pu, which can lead to transversions. The frequency with which such mispairs occur is due mainly to the manifestation of the equilibrium constants for the isomerisation processes required for their formation, that is, keto–enol and amino–imino tautomerisation of the base moieties for the pu–pyr mispairs and both such tautomerisation and anti-syn isomerisation about the glycosyl bond of the nucleoside moiety[8,9] for the pu–pu mispairs. These two classes of mispairs can give rise by single mispairing events to all conceivable substitution mutations involving the commonly occurring nucleotides in DNA (Table 1).

The second major assumption is that there are two opportunities to express the relevant isomeric equilibria involved in particular mispairing events during the process of adding a base pair, first during catalytic incorporation of the new base on the growing strand, and again during a checking step. This results in the relevant equilibria limiting the frequency of mispairing to the level seen in biological systems.

Using these two assumptions, we are able to explain a wide range of mutagenic phenomena, including: how mispairing for each conceivable type of substitution mutation can lead to the frequencies observed *in vivo*; the rate observed for transitions and transversions[10]; the origin of the unidirectional effect of the Treffer's mutator gene on the A–T→C–G transversion[11,12]; and the specificity of the base analogues 5-bromouracil (5-BrU) and 2-aminopurine (2-AP) in inducing transitions but not transversions[13,14]. In what follows, we present the essential features of the hypothesis and the way in which it explains these basic phenomena of mutagenesis. A preliminary report of this work has been made[15].

Chemical plausibility of proposed base pairs

Each of the proposed mispairs with the H-bonding schemes indicated in Fig. 1 was studied by model building and shown to be sterically compatible with a Watson–Crick helix. Moreover, base oppositions corresponding to each of these mispairs have been shown experimentally to take up intrahelical conformations in long polynucleotide helices dominated by Watson–Crick pairs (ref. 16 and M.D.T., H. Chen and J. R. F., unpublished). By contrast, those base oppositions not invoked for mispairing events (pyr–pyr), were experimentally found to take up only extrahelical conformations in such polynucleotide helices (refs 16, 17 and J. Balcerski, M.D.T., and J.R.F., unpublished). Moreover, these oppositions could not be satisfactorily built into a regular DNA helix as base pairs. The proposed pu–pyr mispairs conform precisely to Watson–Crick helia geometry, whereas the proposed pu–pu mispairs require a slight ($\sim$ 9°) distortion of the glycosyl bond angle of the base in the syn configuration without any effect on the glycosyl bond separation distance. Distances between H-bonded atoms are standard. Finally, there is much chemical and crystallographic evidence for the occurrence in certain small molecules of the invoked unusual base tautomers[3–6,18] or nucleoside isomers (reviewed in ref. 19).

Mispairing and DNA synthesis

DNA synthesis seems generally to be a two-step process, involving an incorporation reaction, followed by a checking reaction[20]. In the cases of bacteriophage T4 (ref. 21) and *Escherichia coli*[22] at least, both these catalytic activities reside in a single polypeptide. We assume that the synthetic element of these polymerases does not directly sense the incoming base; instead, the whole DNA synthetic apparatus, consisting of several different proteins in addition to the polymerase[23,24] confers a fixed orientation on the immediate template residue and fixes the orientation and the glycosyl bond separation distance at the growing strand end. Covalent incorporation of a complementary nucleotide is seen as involving nucleoside triphosphate binding to both the polymerase on the synthetic apparatus and the geometrically constrained template residue in a specific way that is determined by H-bonded base pairing.

This binding of monomer is followed by catalysis of phospho-diester bond formation as a natural consequence of complementary base pairing, since only then is the polymerase catalytic site and the 3'-OH of the growing strand in position to attack the α–β pyrophosphate bond of the nucleoside triphosphate. The polymerase-catalysed reaction therefore incorporates any nucleotide when its base is in an isomeric form that allows a complementary pair and discriminates effectively against all others. This mechanism presupposes that once productive pairing or mispairing occurs, isomeric re-equilibration is prevented because the synthetic apparatus, perhaps by inhibiting the breathing of base pairs or by excluding water, makes the H-bonding donor and acceptor sites of the bases inaccessible to the water required for tautomerism. Thus, not only the Watson–Crick base pairs, A–T and G–C, will be incorporated, but also the complementary mispairs, which after another round of replication show themselves as substitution mutations (Table 1).

At this stage, mispairs involving only unfavoured tautomers will have occurred at a level reflecting the sum of the frequencies of unfavoured triphosphate tautomers and of such tautomers in the template residue (since equivalent A–C and G–T pairs occur when either the template or the monomer residues are in the unfavoured tautomeric form). By contrast, mispairing involving syn isomers will occur at a level reflecting the product of the frequencies of the required unfavoured tautomer in the template strand and the syn nucleoside triphosphate. Syn isomers are forbidden in the template strand since, at the outset, those residues are anti in a regular DNA helix[7], and both the stacking in the single-stranded template segment and the rigidity imposed by the synthetic apparatus must create a large barrier to rotation about the glycosyl bond. Thus, those mis-

pairings that lead to transitions will have been introduced to a level of 10^{-4} to 10^{-5} (the frequency of unfavoured tautomers), while those leading to transversions will have been introduced to a level of 10^{-4} to 10^{-5} times ~ 10^{-1} if the syn base is G[8,9] or times ~ 5×10^{-2} if it is A[8,9]. Thus, the fidelity in this synthetic step is greater for transversions than for transitions. These values are, of course, far greater than the biological levels of mutation.

Mispairing and the checking step

Once incorporated, a base pair must be checked to increase the level of fidelity by some mechanism that can remove mispairs with great efficiency. A mechanism by which this might be achieved is suggested by the occurrence of a 3'–5' exonuclease activity in the polymerase moieties of bacteriophage T4 and *E. coli*[21,22], which apparently excises unpaired residues at the growing strand terminus[25]. In higher species there are indications that this activity may be relegated to a separate molecular entity[26].

It is reasonable to assume that the isomeric equilibrium constants are about the same for the residues of the new terminal base pair as for the triphosphates and for the template residues. In the interval between release of the new base pair by the polymerase and the coming into position of the 3'–5' exonuclease moiety, there is renewed opportunity for breathing and accessibility of solvent. Therefore, we expect for transitions the same isomeric equilibria manifest in the synthetic step to be expressed once again during the checking reaction. The checking of transition mispairs should thus lead to a squaring of the fidelity level of the synthetic step, that is, a total fidelity of 10^{-8} to 10^{-10}. For transversions, however, the situation is more complex. For this class of substitutions, also, tautomeric re-

Fig. 1 The complementary base pairs that can be formed from the DNA bases A, G, T, and C are illustrated. The isomeric forms of the bases that predominate in 'physiological' conditions allow only the two Watson–Crick pairs (*a, b*). Tautomerism involving only one proton transfer gives rise, however, to two equivalent pairing schemes each for the pu–pyr pairs, A–C (*c, e*) and G–T (*d, f*) and one scheme each for the pu–pu pairs A–A$_{syn}$ (*g*), G–G$_{syn}$ (*h*), A–G$_{syn}$ (*i*) and G–A$_{syn}$ (*j*). There is no way of constructing a complementary pyr–pyr pair. Note also that the glycosyl bonds of pairs *a–f* are twofold symmetry related regardless of which strand is the fixed template, whereas pairs *g–j* are complementary only when the anti residue is on the template. The enol form of either G or T leads to a G–T pair with three H bonds (*d, f*), whereas the imino form of either A or C makes for A–C pairs with two H bonds (*c, e*). The imino form of A also makes possible A–G (*i*) and A–A (*g*) pairs with two H bonds, provided that the second base G and A, respectively, is in the syn configuration. It should be noted that the A–G pair shown in (*i*) can also be achieved by protonation of the A residue at N1 without tautomerism to the imino form at approximately the same cost in energy. Base pairs involving two H bonds are possible between a tautomerised G and either A$_{syn}$ or G$_{syn}$ (*j, h*). Here, the conventional enol tautomer of G may give rise to a close contact between a 2-amino hydrogen of G and the C8 hydrogen of the opposing A$_{syn}$ or G$_{syn}$, or else this C8 hydrogen may be restricted from H bonding to water. Therefore, a chemically possible minor tautomeric form of G is used instead, an enol, imino tautomer formed by transfer of a 2-amino hydrogen to the 6-oxygen to achieve G–G$_{syn}$ and G–A$_{syn}$.

Purine–Pyrimidine | Purine–Purine

A ≡ T *a* | *b* G ≡ C | A$_{imino}$ = A$_{syn}$ *g* | *h* G$_{enol, imino}$ = G$_{syn}$

A = C$_{imino}$ *c* | *d* G ≡ T$_{enol}$ | A$_{imino}$ = G$_{syn}$ *i* | *j* G$_{enol, imino}$ = A$_{syn}$

A$_{imino}$ = C *e* | *f* G$_{enol}$ ≡ T
Table 1 Pathways for substitution mutations
Pathways are shown whereby every conceivable transition and transversion can occur by single mispairing events that each involve a non-Watson–Crick complementary base pair. Note that whereas transitions can occur with each strand of a base pair, transversions are viewed as occurring only on the strand with the purine template residue since pyr–pyr mispairs are not believed to occur with any significant frequency.
*, Base in a minor tautomeric form; syn, the unfavoured configuration about the glycosyl bond of that residue (see Fig. 1). Arrows indicate rounds of replication.

equilibration of template residues is expected in the checking step; but re-equilibration of the syn configuration of the terminal residue is unlikely because the activation energy for rotation about the glycosyl bond of an incorporated residue stacked on its neighbour should be much larger than it is in the entering triphosphate Consequently, the exonuclease step should enhance fidelity only by the frequency of the minor tautomer in the template residue, that is, by another factor of 10^{-4} to 10^{-4}. Therefore, the total fidelity for transversions will be less than the square of that achieved in the first step, amounting to 10^{-4} to 5×10^{-11}, which is nevertheless greater than that for transitions. It follows that in systems lacking the exonuclease function, substitution mutation rates will be as expected from the first step alone.

Evaluation of the hypothesis

In evaluating the hypothesis, we have considered the literature on nucleic acid chemistry, on the specificity of *in vitro* and *in vivo* nucleic acid biosynthesis and on the mechanism of mutagenesis. We have not found any experimental observations that could not be interpreted in terms of our two principal assumptions. Here, we describe three important types of observations on substitution mutations that illustrate the consistency between hypothesis and observation.

(1) One of the major probes of the mechanisms of mutagenesis involves studies with compounds that induce or enhance the level of spontaneous mutations From the work of Benzer and Freese, in particular, it has been established that certain base analogues are highly specific in inducing transitions only[13,17]. For example, pyrimidines such as 5-BrU, which exhibit a greater tendency to enolise than does their natural counterpart, thymine, behave this way. This selective effect is exactly as expected from our hypothesis since transitions are mediated only by pu–pyr mispairs, whereas transversion mispairs do not involve pyrimidine residues

2-AP is another base analogue that induces only transitions[13,14]. The inability of this purine to induce transversions is of particular interest in view of our proposal that transversions are brought about only by pu–pu mispairs.

The way in which this analogue induces transitions is not difficult to rationalise. Although lacking a substituent on C6, it can interact "normally" with T on the template to form a complementary pair with two H bonds. By tautomerism to the imino form, it can "mispair" with C also by way of two H bonds. The alternative mispairing scheme with C, involving the amino tautomer of 2-AP seems less likely because it allows only one H bond, and the H-bonding tendencies of the internal N1 of the purine and N3 of the pyrimidine would be left unsatisfied.

The lack of potential for pu–pu mispairs involving 2-AP can

Fig. 2 Potential of 2-AP for pu–pu pairing. The inability of 2-AP to form transversion mispairs is illustrated. In the syn configuration, 2-AP can form no H bonds with A (*a*), and whereas a pair with one H bond might be formed with G, it results in a bad Van der Waals' contact (*b*). When in the anti configuration, 2-AP can make but one H bond with either A (*c*) or G (*d*), and then only by tautomerising to the less favoured imino form.

†Ranges are given to encompass several sets of data obtained for the same mutant by Fowler *et al.*[10].

‡For the purposes of these calculations, a value of 1×10^{-1} is taken for the equilibrium frequency of G_{syn} and 5×10^{-2} for that of A_{syn}. The same equilibrium frequency, 5×10^{-5} is assumed for all unfavoured tautomers. If this were actually the case, these calculations would have to take into account that the A–C and G–T pairs each could occur with either the template or the monomer residues in the unfavoured tautomeric form; then, the calculated rates of transitions would have to be raised by a statistical factor of four (two for each step). It is much more likely, however, that the tautomeric equilibria differ for the two members of each pair and differences as small as two–threefold effectively reduce this factor to one. With only one unfavoured tautomer in pu–pu pairs, this factor is also one for transversions.

§These represent the same type of transversion at two different sites within the same gene.

be seen (Fig. 2) to arise from its lack of any substituent on C6. For incorporation opposite a purine, 2-AP must enter in the syn configuration, in which case it can form no H bonds with A (Fig. 2*a*). Against G, the possibility of only one H bond as well as the potential close contact between the C2 amino of the template residue and the C8 hydrogen of 2-AP, which can also interfere with solvation of the C2 amino group, prohibits that pairing as well (Fig. 2*b*). Further, once incorporated, the amino tautomer of 2-AP in the anti configuration of the template strand cannot form any H bonds with either A_{syn} or G_{syn} triphosphates, while the imino tautomer can form pairs which will allow but one H bond (Fig. 2*c* and *d*), which would seem insufficient. Purine analogues that favour syn configurations and have appropriate substituents are, however, expected to induce transversions; and purine analogues of that type which also have a more favourable capacity to tautomerise than A or G should enhance the rate of both transitions and transversions. It may similarly be possible to explain the mutagenic effects of reactive substances that modify bases of intact DNA, thereby altering their capacity either to tautomerise (for example, hydroxylamine[28,29] and Cu^{2+} (ref. 30)) or to be fixed in a syn configuration. Since many such reactive compounds are also carcinogens[31], a correlation is suggested.

(2) Among mutator genes, there is a striking example discovered by Treffers[11] of an allele in *E. coli* that selectively enhances the rate of the A–T→C–G transversion but not the reverse transversion[12]. A consideration of the pu–pu mispairs for these two transversions (Fig. 1*i,j*) and the restriction that the syn residue of those pairs be the entering one, suggests how the unidirectional effect of this mutator comes about. Whereas the forward transversion must be mediated by A_{imino}–G_{syn}, the reversion can only be mediated by $G_{enol,imino}$–A_{syn} and not by the mispair by which it is formed (Table 1). The physiological mechanism by which this mutator is expressed can be imagined to involve a gene coding for some component of the replicative apparatus that allows incorporation of G_{syn} but not A_{syn}. (This would also result in parallel discrimination between the A–A_{syn} and the G–G_{syn} mispairs.) Obviously, a mutator with this kind of discrimination could not affect the rate of transitions because only anti isomers participate in transition

mispairs. The discriminatory characteristics of the Treffers' mutator and others[32,33] clearly correlate with the proposed features that distinguish the mispairs that give rise to transitions from those that lead to transversions.

(3) The rates of transitions and transversions are also consistent with our proposed base-pairing schemes. Specific data against which to evaluate the mechanisms proposed for substitution mutations are provided by a study[10] of spontaneous substitution mutation frequencies for particular sites on the tryptophan synthetase A gene of *E. coli*[14], for which the base-pair changes are known. Those frequencies, determined both in the absence and presence of a mutator gene, *mutD5*, are shown in Table 2. Presented for comparison are the rates we calculate for each transition and transversion from the relevant isomeric equilibria for the proposed complementary non-Watson–Crick mispairs. (For this comparison, it is assumed that *in vivo* mutation rates and the observed frequencies they generate are equivalent. In fact, the observed values should be high, but by no more than a factor of five[32].) Because of the availability of two mispairing routes to both transitions, but only one to each transversion (see Table 1) the rates calculated for the transitions (only) contain a factor of two. In the case of *mutD5* we make the explicit assumption that this mutation, though not in the exonuclease gene[34], has inactivated the checking function. The obvious correlation that this assumption allows us to make between the observed frequencies and the rates calculated, reinforces our confidence in the assignment of the mutD5 phenotype. Thus, it can be seen that the agreement between the observed reversion frequencies for the two transitions examined in the presence of *mutD5* and our estimate for the synthetic step alone is satisfactory; so is that between the frequencies measured in the absence of *mutD5* and our calculated rates. Furthermore, the experimental data agree with our expectation that the total fidelity must approximately equal the square of the frequencies of the unfavourable tautomers only for transitions, where the complementary intermediates are A–C and G–T pairs.

The complexity postulated for transversions is also evident. As demanded by our mechanism and consistent with separating the *mutD5* frequencies from the reversion frequencies observed

in the absence of this mutator, greater fidelity can be seen to be achieved for transversions in the synthetic step than in the checking step. This is because syn isomers should have no role in the checking step. The *mutD5* frequencies are also consistent with our expectation that the synthetic step achieves greater fidelity for transversions than for transitions because of the involvement of syn isomers as well as unfavourable tautomers in transversion mispairs. Indeed, agreement between the observed frequencies in the presence of *mutD5* and the rates calculated for the synthetic step alone for all transversions is quite close, considering that the syn–anti equilibria must be taken into account. Nevertheless, it is apparent that the overall fidelity observed for transversions is somewhat less than we expect. Conceivably, this is because of a lower efficiency in removal of syn than anti residues by the exonuclease. Such a differential effect towards syn compared with anti residues has been observed for other exonucleases[24].

The agreement in both trends and levels between observed and calculated values for the various substitution mutations is encouraging. Nevertheless, we recognise that frequencies are being compared with rates and that the calculations do not take into account such modulating effects as nearest neighbour interactions (which could account for the frequency differences observed in the two cases of the same transversion A–T→C–G at two different loci shown in Table 2) and differences in the relative stability of the various mispairs. Since the calculated rates follow the observed trend, these modulating effects must be small relative to the major factors that we have introduced in the calculations.

The hypothesis we have presented here concerning a new set of complementary base pairs and their relevance to mutagenesis is chemically reasonable and consistent with a large body of biochemical and genetic facts. We therefore believe that the main features of these concepts are correct, though the details may require modification. Experiments explicitly designed to test particular features of the hypothesis are needed to assure their validity. We are initiating some, and we hope that others will be prompted to design additional tests.

The wider concept of complementary base pairing that has been introduced here has relevance to other problems in molecular biology. In the accompanying paper[36], we address the question of their role in protein synthesis. Later reports will deal with their relevance in other contexts.

Base pairing and fidelity in codon–anticodon interaction

Michael D. Topal & Jacques R. Fresco

Department of Biochemical Sciences, Princeton University, Princeton, New Jersey 08540

Base pairing in codon–anticodon interaction has been investigated in order to understand the basis on which particular base pairs have been selected for or against participation at the wobble position and the basis for codon–anticodon infidelity.

STUDIES of the genetic code revealed that the Watson–Crick pairing rules for DNA[1] are only followed strictly for the first two base pairs of codon–anticodon interaction[1]. Much of the pairing at the third codon position also involves the normal Watson–Crick base pairs, A–U, and G–C, but for several codon–tRNA interactions, non-Watson–Crick pairs are clearly required. This led Crick to propose that the pair at the 3′ end of the codon can deviate (from complementary helix geometry) or "wobble" within arbitrary limits (to the glycosyl bond separation distance and dihedral angles) that are consistent with the additional pairing interactions suggested by the code.

Our reconsideration of this problem takes into account the chemical features of the bases and the stereochemistry of non-Watson–Crick complementary base pairs, described in the accompanying paper[3], that have allowed us to suggest mechanisms for mispairing in replication. We deduce that the "wobble" pairing schemes for G–U, U–G and U–I must be as proposed by Crick[4], but that an alternative base-pairing scheme for A–I is a more suitable codon–anticodon interaction. We also show that in a manner similar to the way they act in nucleic acid biosynthesis[3], complementary non-Watson–Crick base pairs contribute to the natural level of infidelity in protein synthesis. A preliminary report of this work has been made[5].

Base-pairing alternatives

The wider set of complementary base pairs described in the accompanying paper[3], utilises base tautomers (enol and imino) and nucleoside isomers (syn) that are unfavoured in aqueous solution. With U substituted for T, we must consider in the case of protein synthesis the pairs that can be formed in this way from the four characteristic bases of nucleic acids and in addition, C–I, U–I, G–I and A–I, since inosine is the first

anticodon residue of many tRNAs[6]. Figure 1 shows complementary pairing schemes (studied by model building) containing I; of these, only C–I utilises the preponderant isomers. The ability of such base oppositions to take up intrahelical arrangements within helices dominated by Watson–Crick pairs has also been experimentally demonstrated, though the actual H-bonding schemes have not been ascertained (ref. 7, and M.D.T., H. Chen and J.R.F., unpublished).

As shown in Fig. 2a–d, all the pairs covered by Crick's wobble-pairing schemes make use of the favoured forms of the residues, and the glycosyl bond separation distances are close to the 10.9 Å typical of a complementary pair, for all except A–I, for which it is 12.8 Å. Assuming that the codon constitutes a fixed template, this longer separation distance exaggerates the extent of backbone relocation required of the anticodon chain at the wobble position. In contrast, the amount of chain relocation required for those wobble pairs with the near-normal separation distance appears to be negligible for the short codon–anticodon helical array.

Additional wobble pairs—A–C (and C–A) can be built with the same stereochemistry as their G–U and U–G counterparts (Fig. 3a,b) only with a single H bond. They are unlikely to occur since this arrangement would lead to one unfulfilled H-bond

the syn residue lies in a complementary position; but when the template residue is syn, the opposite member takes up a "wobble" position. Thus, the additional pu–pu wobble pairs in Fig. 3 have their complementary inverse pairs; for example, wobble pair A_{syn}–$G_{enol,imino}$ (Fig. 3c) has its complementary pair inverse $G_{enol,imino}$–A_{syn} (Fig. 1j of accompanying paper[3]).

Base pairing in codon–anticodon interaction

From these considerations it is difficult to decide which type of pairing is most relevant to codon–anticodon interaction. Although the complementary non-Watson–Crick pairs are sterically more acceptable, the thermodynamic cost of utilising the unfavourable tautomers or isomers they require could be greater than the cost of a small helix distortion at the wobble position. We have found it possible to choose between these alternatives with the aid of the following three assumptions.

(1) The ribosome limits wobble-pairing schemes to those that minimise backbone distortion and it constrains the message as a template. Studies of coding fidelity with ribosomal mutants[8] and drugs such as streptomycin[9,10] indicate that the ribosome does impose steric constraints on codon–anticodon interaction.

(2) The ribosomal cavity for codon–anticodon interaction precludes tautomerism and protonation therein. Complementary
Fig. 1 Complementary base-pairing schemes involving the anticodon I residue. a–c, Pyrimidine–purine; d, e, purine–purine. The C–I pair (a) is in all respects the equivalent of a standard Watson–Crick complementary pair. Other non-Watson–Crick complementary pairs are shown in Fig. 1 of the accompanying paper[3] where, however, T is used in place of U. Note that the stereochemistry for the pu–pyr pairs that involve an unfavoured tautomer in either member conforms precisely to that of the Watson–Crick pairs, whereas that for the pu–pu pairs requires a small deviation, ∼ 9°, in the glycosyl bond angle of the anticodon residue, but no alteration in glycosyl bond separation distance. Wherever shown, arrows indicate the source of a proton that has been transferred in the tautomeric shift from a favoured to an unfavoured isomer.

acceptor site, or two H bonds made possible by protonation of the A member. Additional pu–pu wobble pairs are also conceivable (Fig. 3c–e) which make use of combinations of syn isomers and unfavoured tautomers. In particular the A–I pair shown in Fig. 3e, which makes use of a syn residue in the codon position has a near-standard glycosyl bond separation distance, instead of the much longer one proposed by Crick (Fig. 2b).

When one member of a pu–pu pair has its backbone location fixed as part of a template, an interesting asymmetry exists if one member is syn (Fig. 4). When the template residue is anti,

mispairing requires unfavoured tautomers which can occur only by a proton jump by way of water molecules proximal to the donor and acceptor atoms of the base. Binding by the ribosome of both messenger and tRNA must inhibit breathing of the codon–anticodon complex. This alone will preclude tautomerism since water is excluded between paired bases. Moreover, when tRNA and mRNA enter the cavity, bulk water that fills such space in their absence will be displaced, so that in the immediate vicinity of codon–anticodon negotiation, the amount of free water will be greatly reduced. If re-equilibra-

tion to minor tautomers is thereby precluded, miscoding due to complementary mispairs (Fig. 1 of accompanying paper[3] and Fig. 1 here) will be kept at a very low level (assumption (3)). Therefore, the specificity at all codon-anticodon positions must depend primarily on the predominant keto and amino forms of the bases.

(3) Tautomeric equilibria nevertheless play a part in codon-anticodon interaction to the extent that the message and tRNA manifest these equilibria in solution. Whereas the ribosome will prevent mismatched oppositions from becoming complementary mispairs (assumption (2)), they must also lock in those unfavoured tautomers that have matched up to form such mispairs (for

occurs at the tRNA wobble position[17] and there are 16 codons with U in the third position. The different geometry for G-U raises the question of whether this pair is also used. Comparison of the code with anticodons established in experiments with sequenced tRNAs (see Table 1 of ref. 17) suggests that G-U may not be required. Thus, Gln, Lys and Gly, with code words that have A or G in the third position (CAA and CAG for Gln, AAA and AAG for Lys, GGA and GGG for Gly), each have two corresponding tRNAs in the same species[18], one with a modified U and another with C in the wobble position. On the other hand, an unusual case has been found in which an ochre suppressor tRNA (UUA) reads the amber codon (UAG) in vivo

Fig. 2 Wobble-type or non-complementary H-bonded base pairs proposed by Crick[4] for codon-anticodon interaction. The codon or template residue is always shown on the left, and the horizontal line from the Cl' carbon of the codon residue extends to the location of the Cl' carbon of the anticodon residue if the latter were complementary. Note that only keto and amino tautomeric and neutral forms of the bases are used for the pairing schemes proposed by Crick. In each case, the twofold symmetry that relates the Cl' carbons of the two residues of a complementary pair is absent. Generally, this leads to only a small amount of backbone displacement because the glycosyl bond separation distance is maintained close to that of a complementary helix. In the case of A-I (b), however, that distance is nearly 2 Å greater, which results in excessive backbone displacement.
example, A_{imino} with C, Fig. 1 of ref. 3). Hence, the low frequencies of minor tautomers that both interactants must contain will be frozen by the ribosome and be expressed. This will give rise to a background in vivo level of spontaneous miscoding involving all complementary mispairs since they all involve minor tautomers (G-U, A-C, U-I, G-I, A-I, A-A, A-G, and G-G). Miscoding should therefore occur at all three positions at frequencies that depend on the relative occurrence of the isomers required in the mispairs: for pu-pyr, 10^{-4} to 10^{-5} (tautomeric frequency)[11-14]; for pu-pu, the latter values are lower, 10^{-5} to 5×10^{-7} because pu-pu pairs involve syn isomers[15,16] which occur at a frequency of $\sim 10^{-1}$ for G_{syn} and $\sim 5 \times 10^{-2}$ for A_{syn}, as well as unfavoured tautomers.

From these assumptions we can evaluate pairing schemes for those non-Watson-Crick base oppositions that prevail in the wobble position and can then deduce the nature of the mispairs that lead to infidelity. Throughout, base pairs are denoted with the codon residue on the left.

Pairing in the wobble position

U-G, U-I-. Since tautomerism is precluded, Crick's wobble-pairing schemes must prevail. With the codon as template, the glycosyl bond of G or I at the wobble anticodon position will be displaced to the same extent and in the same direction.

G-U-. The deviation of the anticodon residue for wobble G-U, though equal to that for wobble U-G, is opposite in direction of displacement of the anticodon glycosyl bond (Fig. 2a,c). U-I and U-G are required by the code since A never

very effectively[19]. In this case at least, G-U has a role even though it is sterically different from U-G.

A-I-. We suggest instead of Crick's "long" wobble pair (Fig. 2b), one in which A in the codon is syn, while I in the anticodon is anti (Fig. 3e). This arrangement, observed in a cocrystal of 9-ethyl-8-bromoadenine and O-ethyl-8-bromohypoxanthine[20], uses favoured tautomers and allows a standard glycosyl bond separation distance[21]. With codon as template, however, only wobble geometry is possible (Fig. 4). This arrangement ought to form with acceptable frequency if the 2 kcalorie mol^{-1} (refs 15, 16) cost of A_{syn} is not increased within the ribosome.

Evidence for an A-I pair in protein synthesis is not definitive. In vitro coding data [22,23] are consistent with its occurrence, but subject to artefacts due to the unnatural levels of divalent cations used[24]. Moreover, it seems that there are two tRNAs with I in their anticodons (one for Val and one for Ser) that are not needed for interaction with codons (GUA and UCA, respectively) that have A in the third position[17] since isoacceptor tRNAs exist with U in place of I. Because these isoacceptors have not yet been demonstrated in the same species, however, their bearing on the question is uncertain. Conceivably, a tRNA with I instead of U in the anticodon is required to prevent the ambiguous reading of the Met codon, AUG, by a tRNA[Ile] that normally reads AUA. It is now apparent[25,26], however, that ambiguous recognition of G instead of A is avoided by replacing U with s^2U. In any case, if A-I occurs in vivo, then the A_{syn}-I wobble arrangement would seem to be more favourable than Crick's[4].

A–G–. Although this pair occurs in long Watson–Crick helices (M. D. T., H. Chen and J. R. F., unpublished), the code forbids it at the wobble position. Crick suggested[4] that the A–G counterpart to the A–I wobble pair does not occur because the amino group of G cannot H bond even to water. If A–I has a role in protein synthesis, this presumed constraint would be equally relevant to the A_{syn}–G counterpart to the proposed A_{syn}–I pair. Moreover, it seems that a 2-amino hydrogen of G eclipses the C8 hydrogen of A_{syn}. In either case, a tautomeric shift (2-amino→6-oxygen) could remove this constraint. As noted, however, such shifts are precluded within the ribosome. If instead, A–I does not occur *in vivo*, then both A–I and A–G may be excluded by the same ribosomal constraints that prevent A from either becoming syn or pairing with a long glycosyl bond separation distance.

A–C, G–G, G–A, C–A–. These pairs also occur in long Watson–Crick helices (M.D.T., H. Chen and J.R.F., unpublished), even though they are prohibited by the code[27].

the U–G, G–U and U–I pairs there (because these pairs could not then occur with the high frequency required), while the original H-bonding schemes of the wobble hypothesis are correct except for the case of A–I. A more reasonable wobble-pairing arrangement is proposed for A–I that is consistent with the absence of the analogous A–G pair.

Mispairing in codon–anticodon interaction

We now evaluate the role of non-Watson–Crick pairs as a source of infidelity in protein synthesis. It is evident from the prohibition of wobble pairs at the first two codon positions that the ribosome effectively screens out non-complementary pairs from those positions. In normal *in vivo* conditions, however, there ought to be a background level of miscoding that reflects the frequency of residue isomers on both message and tRNA before they enter the ribosome (assumption (3)), that can give

C = A⁺   *a*   *b*   A⁺ = C

A_{syn} = $G_{enol, imino}$ *c*   *d* $G_{enol, syn}$ = I

A_{syn} = I   *e*
Fig. 3 Additional wobble-type base pairs for consideration in codon–anticodon interaction. A–C and C–A (*a,b*), which do not normally occur in codon–anticodon interaction, can only make this type of pair with two H bonds when one of its members is protonated. Among the pu–pu pairs, all involve one member in the syn configuration, but A_{syn}–I (*e*) is unique in not requiring an unfavourable tautomer. The requirement for an unfavoured tautomeric shift in the case of A_{syn}–$G_{enol, imino}$ (*c*) is not to enable the H bonding itself, but to remove an otherwise interfering interaction of the 2-amino of G with the C8 hydrogen of A.

Presumably, A–C and G–G do not serve at the wobble position because their pairing schemes require minor tautomers in high frequency, and G–A and C–A are irrelevant since A never occurs in the wobble position of tRNA[a].

U–U, C–C, U–C, C–U–. These do not occur in long Watson–Crick helices (J. Balcerski, M.D.T. and J.R.F., unpublished), and are forbidden by the code. Their occurrence would require a large backbone distortion that would enhance electrostatic repulsion of the phosphates brought closer together. The exception of U–U[a]–oxacetate pairing[aa] must be due to some unique effect of the substituent on C5 of the pyrimidine on the tRNA.

We conclude that schemes for pairing at the wobble position that require minor tautomers of bases[a,a] cannot account for

rise to complementary mispairs at all three codon positions. Mispairing at the wobble position could possibly also arise from the additional wobble pairs proposed in Fig. 3, since the ribosomal constraints must be relaxed somewhat to allow "normal" wobble at that position. Higher levels of miscoding due to mutations that reduce the ribosomal constraints or to drugs with similar consequences should be superimposed on this natural level of infidelity. Still higher levels of miscoding should occur *in vitro* when unnatural concentrations of cations or other artefactual conditions are used that overcome the specificity of the codon–anticodon interaction. Miscoding in this instance could involve an even wider range of non-Watson–Crick base oppositions, particularly if only two base pairs have to be stabilised.
Template

Fig. 4 The steric relationship between a complementary pu–pu pair, when one residue has its locus fixed as part of a template, and either member is in the syn configuration. The particular example shown is that of an A–I pair with A as template (top) and I as template (bottom). Whereas the former meets complementary base-pair glycosyl bond separation distance without a significant dislocation of the backbone segment to which the non-template base is linked, wobble-type dislocation results when the syn residue is on the template.

Evaluation of the mispairing hypothesis

In vivo measurements of suppression of polar mutations in structural genes for β-galactosidase[30] and ornithine trans-carbamylase[8] and of the frequency of incorrect insertion of amino acids into rabbit haemoglobin and chick ovalbumin[31,32] lead to values of infidelity as high as 10^{-4} per amino acid site. This is consistent with what is expected from the frequency of the most favoured complementary mispairs, that is, those requiring only unfavoured tautomers (10^{-4}–10^{-5}). Thus, the *in vivo* infidelity is of a level that might be expected from the frequency of the minor tautomers in both message and tRNA before their interaction within the ribosome.

The *in vivo* level of infidelity is the sum of errors in several steps. Errors due to complementary mispairs will contribute a maximum frequency of 5×10^{-5} per residue in both transcription and codon–anticodon interaction. This is equivalent to an infidelity frequency of 3×10^{-4} per amino acid site, ignoring degeneracy of the code, which would lower this value. The indications are[33] that amino acid activation and aminoacylation together contribute another factor of 10^{-4}, for an overall error level of 4×10^{-4}, which is consistent with that measured *in vivo*. Although kinetic proofreading[34] of the codon–anticodon interaction may be necessary to screen out errors from such effects as two-base pair interactions, there is no obvious basis and no apparent need for proofreading of infidelity caused by complementary mispairs. This is because the mispairs are frozen within the ribosome and the level of infidelity to which they give rise is not greater than that contributed by the other steps of protein synthesis. Indeed, energy used for proofreading at this stage would seem wasteful.

If complementary mispairing is a source of errors in codon–anticodon interaction, there should be a defined pattern of miscoding which involves all complementary mispairs, that is, U–G, G–U, A–C, C–G and A–G at all codon positions, A–A, G–A and C–A at only the first and second positions (since

tRNAs never contain A in the wobble position), and G–I at only the third (since I only occurs at the wobble position). While pyr–pyr pairs should not occur at any codon position, additional A–C, A–G and G–I wobble-type pairs (Fig. 3) may possibly occur at the third position. The only *in vivo* coding data[30] confirms the occurrence of G–U, and A–C in both the second and third codon positions, with the frequency of background suppression due to A–C occurring at the 0.01 % level, which is consistent with the frequency of required tautomers. A higher value was observed for G–U, however; reasons for this are not apparent.

In vitro studies of codon–anticodon interaction do not provide a basis for evaluating the mispairing hypothesis. The errors occur at 10–100-fold or greater frequency than *in vivo*[24], presumably because of artefactual stabilisation of a variety of "nonspecific" interactions.

This investigation of base pairing in codon–anticodon interaction provides a basis for refinement of the wobble hypothesis and a chemical basis for infidelity in the process. Although our approach follows that which we used to investigate base pairing in nucleic acid biosynthesis[3], the present analysis is less satisfying because of the paucity of data against which to evaluate our hypothesis on base pairing in protein synthesis, but the concepts presented provide a basis for experimental focus.

This study has led us to consider the role of the ribosome in protein synthesis. It seems that the specificity of codon–anticodon interaction derives as much from the ribosomal constraints as from the limited degree of specificity that can come from the base-pairing interactions. The development of such constraints, which assure biologically acceptable levels of fidelity and efficiency of protein synthesis, may have been crucial during evolution of the ribosome.

Formation of stable crystalline enzyme–substrate intermediates at sub-zero temperatures

Anthony L. Fink & Ahmed I. Ahmed

Division of Natural Sciences, University of California, Santa Cruz, California 95064

Sub-zero temperatures can be used to trap intermediates in enzyme-catalysed reactions using suitable cryosolvents. The feasibility of obtaining such intermediates in the crystalline state for X-ray diffraction studies has been demonstrated with several proteases, using specific substrates and optimal pH.

Two problems in the study of enzyme mechanisms are the rapidity of the reaction and the low concentration of intermediates present in steady-state conditions. These cause technical difficulties in the determination of events occurring during the dynamic processes of catalysis. The existence and structure of intermediates in the catalytic reaction pathway must be known before the mechanism can be ascertained, and the great catalytic efficiency of enzymes can be explained. X-ray crystallography is one of few techniques that can yield structural data about such intermediates at the desired resolution. Unfortunately X-ray diffraction is limited in that it is essentially a static procedure and requires stable, crystalline compounds. Recent developments, however, suggest that this might be overcome at sub-zero temperatures.

It has been known for some time that many enzymes are catalytically active in aqueous organic solvent systems at sub-zero temperatures[1-6]. We have been exploiting different free energies and enthalpies of activation for the different steps in the overall enzyme-catalysed reaction to accumulate intermediates at very low temperatures. The basis of this approach is that when the reaction is initiated by mixing enzyme and substrate at a very low temperature the rates of intermediate transformations with sufficiently high activation energies will become negligible. Consequently, turnover will not occur and intermediates will accumulate. Thus instead of steady-state turnover, a series of reaction steps will be seen, each corresponding to the transformation of one intermediate into

another as the temperature increases. Eventually a temperature will be reached that is sufficiently high for turnover to occur. As long as the temperature is sufficiently low to avoid turnover, the enzyme will be trapped in the form of an intermediate or intermediates. The method is discussed in more detail elsewhere[9]. For several enzymes it has been possible to demonstrate the accumulation of intermediates found in the reaction with kinetically specific (good) substrates at optimal pH by this technique[3,6,10-15]. In these studies dissolved enzyme and various spectral techniques were used to detect and characterise the trapped intermediate.

We have investigated the feasibility of using sub-zero temperatures to obtain the trapped enzyme–substrate intermediates in crystalline form and sufficiently stable for high resolution X-ray diffraction studies. The intermediates used were acyl-enzymes formed from serine proteases. The reaction scheme for these enzymes can be represented by equation (1), in which ES is the initial non-covalent Michaelis complex, I_P and I_{NP}

$$E + S \rightleftharpoons ES \rightleftharpoons \left\{ \begin{array}{c} I_P \\ \updownarrow \\ I_{NP} \end{array} \right\} \overset{k_2}{\rightleftharpoons} EA \overset{k_3}{\longrightarrow} E + P_2 \qquad (1)$$
$$+$$
$$P_1$$
represent possible subsequent productive and non-productive intermediates respectively, EA is the acyl-enzyme intermediate and k_2 and k_3 are the rate constants for acylation and deacylation.

The serine proteases were chosen for several reasons. We have shown that sub-zero temperatures and 65% aqueous dimethyl sulphoxide or 70% aqueous methanol have no adverse effects on the structural and catalytic properties of chymotrypsin and trypsin[6,7]. We have also shown that essentially stoichiometric amounts of acyl-chymotrypsin, formed from specific p-nitrophenyl esters, can be isolated at sub-zero temperatures[6]. For specific ester substrates of chymotrypsin the acylation reactions can be orders of magnitude faster than

deacylation at temperatures below −40 °C in 65% aqueous dimethyl sulphoxide[6,7,10,11]. We have also detected and accumulated intermediates in addition to the acyl-enzyme in the reactions of chymotrypsin, elastase and trypsin with specific substrates[6,7,10,11]. Since our studies suggest that these intermediates are present, although not readily detected, when the reactions are carried out in "normal" conditions, knowledge of their structure is desirable[10].

Crystals of chymotrypsin and elastase have been shown to be catalytically active in aqueous solution at above-zero temperatures[16-23]. Preliminary studies on the effects of crystal size on the reaction rate and substrate diffusion in enzyme crystals have shown that catalytic rates and accessible active-site concentrations depend on crystal size[24-26]. Crystallographic studies have been carried out on acyl-enzymes formed by the reaction of nonspecific substrates with chymotrypsin[23], and on enzyme-'substrate' complexes formed by reaction of serine proteases with virtual substrates[22], peptide competitive inhibitors[17,18], peptide chloromethyl ketones[16] and protein inhibitors[27]. These investigations have greatly furthered the understanding of the mechanisms of action of these enzymes. But the fact that the derivatives used were sufficiently stable for X-ray diffraction implies that the relative positions of the enzymes' catalytic groups and the substrate were not optimal.

Petsko[28,29] has shown that X-ray diffraction studies of enzymes at sub-zero temperatures using aqueous–organic solvent systems have advantages, such as greatly decreased radiation damage. If X-ray diffraction techniques are to be applied to crystalline, trapped enzyme–substrate intermediates the following requirements must be met. At least 25 per cent of the enzyme must be in the form of the intermediate in order to attain sufficient intensity in electron density difference maps. Only free enzyme or the desired intermediate should be present. Mixtures of more than one type of intermediate are undesirable, and the crystalline intermediate, once formed, must be stable for a sufficiently long period for diffraction data to be collected, probably a minimum of 1–4 d for high resolution studies. We have shown, using sub-zero temperatures, that intermediates such as acyl- and glycosyl-enzymes satisfy the latter two requirements[6-8,10-13]. This and the accompanying article[30] confirm the validity of the cryoenzymological approach for obtaining detailed structural information on enzyme–substrate intermediates.

Acyl-A enzyme formulation in solution

p-Nitrophenyl ester substrates are well suited for studies of acyl-enzyme formation and breakdown in the serine proteases. The chromophoric nitrophenol moiety provides a simple means of monitoring the reaction. The smaller rate constant and larger energy of activation for the deacylation step mean that at appropriately low temperatures not only is the rate of acylation much faster than that of deacylation but also that the latter can be essentially zero.

The acylation and deacylation reactions of the following enzyme–substrate combinations were studied in the range −20 to −70 °C using aqueous dimethyl sulphoxide and aqueous methanol cryosolvents: α-, δ-, and γ-chymotrypsin with N-acetyl-L-tryptophan p-nitrophenyl ester (AcTrpP), trypsin with Nᵉ-carbobenzoxy-L-lysine p-nitrophenyl ester, and elastase with N-carbobenzoxy-L-alanine p-nitrophenyl ester (ZAP) and N-acetyl-L-alanyl-L-alanyl-L-alanine methyl ester.

Rates of acylation and deacylation (turnover) were determined for the p-nitrophenyl ester substrates by monitoring the release of p-nitrophenol at 340 or 350 nm. The concentration of acyl-enzyme formed was estimated from the amount of p-nitrophenol released in the first-order acylation reaction. For dissolved enzyme experiments, the enzyme stock solution was diluted 1:4 with cryosolvent at 0 °C and then added to the substrate solution at the desired sub-zero temperature.

For each enzyme, the rates of acyl-enzyme formation and breakdown, and the maximum concentration of acyl-enzyme formed were determined in various conditions. Some representative results of such experiments with dissolved enzymes are given in Table 1. In each case the acylation was first order and very much faster than deacylation. Deacylation was much too slow for the reactions to be followed to completion in a convenient time. In Table 1 the deacylation rates are reported in the form of the observed initial velocities (v_i). The substrate concentrations used were of the order of K_m; hence, dividing v_i by the acyl-enzyme concentration gives an approximate value of the microscopic deacylation rate constant, k_3 in equation (1).

For each enzyme there are conditions in which the rate of deacylation is sufficiently slow that negligible amounts of acyl-enzyme would be lost during the time necessary for the collection of diffraction data. For example, for elastase in 70% aqueous methanol at pH* 5.7 the amount of dissolved N-carbobenzoxy-L-alanyl-elastase which will hydrolyse in 24 h is 0.4% at −70 °C, 2.2% at −60 °C, and 11.0% at −50 °C. Acyl-enzyme concentrations approximately stoichiometric with the enzyme concentrations were only obtained at temperatures sufficiently low that no turnover was observed.

In conditions in which turnover occurs, the amount of enzyme converted into acyl-enzyme is predicted to be proportional to the substrate concentration unless it is much greater than K_m (ref. 31). This was observed to be the case. For example, with elastase and ZAP the fraction of total enzyme in the form of acyl-enzyme was a function of temperature; at increasingly higher temperatures, as the deacylation rate increased, the proportion of acyl-enzyme decreased. Consequently to obtain the maximum concentration of acyl-enzyme, it is essential to adjust pH* and temperature such that deacylation is negligible.

Experiments with dissolved α-, δ-, and γ-chymotrypsin indicate that approximately stoichiometric concentrations of acyl-enzyme can be obtained in the −50 °C to −70 °C range, using 65% aqueous dimethyl sulphoxide at pH* 5–8. Since both acylation and deacylation have similar pH dependencies, the relative ratio of rates of acylation to deacylation is essentially pH independent. In the conditions used, the rates of acylation were several orders of magnitude greater than that for deacylation. The rates of deacylation, especially at temperatures below −50 °C and at low pH*, were so slow that the acyl-enzymes could be made stable for a time scale of weeks or longer.

Because aqueous dimethyl sulphoxide cryosolvents are much

more viscous, they are less desirable than the corresponding methanol solvents[32]. The nucleophilicity of methanol towards acyl-chymotrypsins, however, is much greater than that of water[33], which suggested that in experiments at sub-zero temperatures deacylation would be much faster with aqueous methanol than with aqueous dimethyl sulphoxide for the same temperature. As Table 1 shows, with γ-chymotrypsin and AcTrpP the deacylation rate was about 15 times greater in the methanol solvent. This value is in good agreement with that calculated from the data of Bender *et al.*[33] obtained at 25 °C.

Crystalline acyl-enzyme formation

As preliminary attempts to crystallise the trapped acyl-enzymes at very low temperatures were unsuccessful, we started with the enzymes already in the crystalline state. Crystals of the enzymes were prepared as described before[34,35], except that γ-chymotrypsin was crystallised using 40 % saturated ammonium acetate, pH 5.6, rather than ammonium sulphate[34]. Crystals were grown in small capillary tubes, closed with dialysis membrane[36]. For most experiments with crystalline enzyme the procedure was as follows. One or more crystal(s) of the enzyme was added to the cryosolvent, either directly at 0 °C, or stepwise[29]. The crystal(s) was then added to the substrate solution at the desired temperature or vice versa. The reaction was either monitored directly, or samples were removed and analysed spectrophotometrically for *p*-nitrophenol. For experiments with elastase and the peptide ester substrate, acylation was followed by assaying for free elastase using ZAP at −40 °C. The solubilities of crystalline enzymes were determined by assaying samples from control experiments in which the substrate had been omitted. All experiments were carried out in conditions of excess substrate.

The precision of the values of the active-site occupancies of the crystals is not very high because of the difficulty of ascertaining the concentration of active sites in the crystal. The most accurate values were obtained when the crystalline acyl-enzyme deacylated at higher temperatures and was then dissolved in a suitable solvent for determination of total protein concentration. In conjunction with active-site normality titrations of the same batch of enzyme, this facilitated estimation of the active-site concentration in the crystal.

The data given in Table 2 are for experiments in which the enzymes were added in the crystalline state. With the exception of α-chymotrypsin, sufficient active-site occupancy was achieved for satisfactory X-ray diffraction studies. Crystalline and dissolved acyl-enzymes were shown to possess full potential catalytic activity when their temperatures were raised to 0 °C and the rates of turnover were measured.

Ammonium acetate was added to reduce the solubility of chymotrypsin and trypsin in 65 % aqueous dimethyl sulphoxide. Experiments with dissolved enzyme indicated that the catalytic reaction was essentially the same in both 65 % aqueous dimethyl sulphoxide (μ = 0.1 M) and in 52 % aqueous dimethyl sulphoxide, saturated (at −80 °C) with ammonium acetate, at the same temperature and pH*.

α-Chymotrypsin crystallises in a dimeric form in which the active site is blocked by the adjacent molecule. This packing geometry hinders access by any but the smallest of substrates or inhibitors[16,38]. Our observation that only 3 % of the active sites of crystalline α-chymotrypsin was occupied using AcTrpP compared with 20 times as much with γ-chymotrypsin in similar conditions, not only is in accord with expectations but serves as a valuable control. Active-site occupancies with crystalline α-chymotrypsin of 15–20 % at 25 °C have been claimed with similar substrates[19]. Attempts to crystallise δ-chymotrypsin have been unsuccessful[37], and so it was used in the amorphous state. The high active-site occupancy observed with this physical form of the enzyme is in accord with predictions that in very small crystals diffusion into the crystal is not limiting[24-26]. The active-site occupancy obtained with γ-chymotrypsin crystals is of the desired order for X-ray diffraction experiments.

As might be expected the results with trypsin are very similar to those for γ-chymotrypsin. For the crystalline enzyme the active-site occupancy and acylation–deacylation rate ratio indicate the suitability of trypsin for diffraction studies using aqueous dimethyl sulphoxide and temperatures below −50 °C. The explanation for the lower active-site occupancies with γ-chymotrypsin and tryspin is probably due to errors in determining the concentration of the active enzyme in the crystals.

For elastase a polypeptide ester substrate as well as a *p*-nitrophenyl ester was used. Both the molecular size and the kinetic parameters, k_{cat} and K_m, are very similar for ZAP and *N*-Ac-Ala-Ala-Ala methyl ester[39,40]. We have also found that non-covalent enzyme–substrate intermediates involving elastase and *N*-succinyl-Ala-Ala-Ala *p*-nitroanilide can be accumulated in a similar fashion to the acyl-enzyme (unpublished results). Most of the elastase experiments were carried out using aqueous methanol. The solubility of elastase was found to be much less than that of trypsin and chymotrypsin in the cryosolvents used. The results from experiments using crystalline elastase indicated that the active site occupancy for the peptide substrate was at least equal to or better than that for the *p*-nitrophenyl ester. The acylation reaction for the latter substrate with the largest enzyme crystals seemed biphasic (Table 2). The data obtained show that substantial concentrations of crystalline acyl-elastases can be obtained in 70 % aqueous methanol at the pH-optimum and that at temperatures below −60 °C the acyl-enzymes will be stable for several days. Good agreement in the observed rates of acylation and deacylation for crystalline elastase with ZAP was found in the results reported here and those obtained in the diffraction experiments[30]

Previous studies have indicated that at 25 °C the rates of reactions catalysed by crystalline enzymes range from 100 to 0.3 % of the rate with the enzyme in solution[24-26]. At sub-zero temperatures we observed substantially slower acylation when the crystalline enzymes were used than in the corresponding reaction with dissolved enzyme. For example, acylation was approximately 20 times slower with the crystalline enzyme for elastase and about 15 times slower for γ-chymotrypsin. As Table 2 shows, no deacylation was observed with the crystalline acyl-enzymes over 2–4-d periods at temperatures below −40 °C. This observation is in contradiction to the predicted deacylation rates based on the experiments using the dissolved acyl-enzymes (Table 1) and suggests that the intrinsic rate of deacylation is slowed down in the crystal by an amount at least comparable with that of the acylation. One interpretation of this result —that the crystal lattice forces are responsible and perhaps hinder the deacylation by impeding a conformational change— is supported by the observation that in crystalline trimethyl-acetyl-chymotrypsin (ambient temperature, aqueous buffer) the rate of deacylation is 50–100 times slower than in solution, and that the crystals shatter after 5–10 % deacylation (F. J. Kézdy, personal communication). These observations are not in accord with the report that indoleacryloyl-chymotrypsin had identical rates of hydrolysis when in solution or crystalline phase[42].

In conclusion, the results of this investigation show that temperatures in the −50 °C to −70 °C range (depending on the pH*), in conjunction with suitable cryosolvents, can be used to accumulate essentially stoichiometric concentrations of dissolved acyl-enzymes from serine proteases and specific substrates. Furthermore, substantial concentrations of acyl-enzymes in the crystalline state can be obtained in a similar manner. These experiments can be done at pH values corresponding to maximum activity. The accumulated acyl-enzymes (dissolved or crystalline) are stable for periods of days to months. By the choice of appropriate pH* and temperature the active-site occupancies and negligible deacylation rates necessary for X-ray diffraction studies can be attained. Confirmation of the results and predictions of this study are given in the accompanying article[30] concerning crystallographic studies of an acyl-elastase.

Alber for carrying out preliminary experiments and for stimulating discussions, and the NSF and NIH for financial support.

Crystal structure of elastase–substrate complex at −55 °C

T. Alber*, G. A. Petsko & D. Tsernoglou

Department of Biochemistry, Wayne State University School of Medicine, Gordon H. Scott Hall of Basic Medical Sciences, 540 East Canfield Avenue, Detroit, Michigan 48201

The structure of a specific acyl-enzyme intermediate in the elastase-catalysed hydrolysis of N-carbobenzoxy-L-alanyl-p-nitrophenol ester has been determined by X-ray diffraction at 3.5 Å resolution. The acyl-enzyme was stabilised by cooling the crystal to −55 °C during substrate addition and data collection.

THE structure of a specific acyl-enzyme intermediate in the catalytic reaction of a serine protease has been determined by the X-ray diffraction at sub-zero temperatures. The use of a fluid cryoprotective solvent methanol–water, allowed addition of the substrate to the crystalline enzyme at −55 °C. At this temperature an acyl-enzyme formed within 1 d but was stable for more than a week. This work demonstrates the potential of low temperature protein crystallography for directly determining the details of the interactions of enzymes with their actual substrates.

Cryoenzymology

Protein crystallography is the most powerful technique for observing the interactions of enzymes with small molecules at atomic resolution. Since protein crystals contain intermolecular channels filled with the liquid of crystallisation, it is possible to diffuse small molecules into the crystals. There they can bind to the protein molecules if their binding sites are not blocked by molecule–molecule contacts. The crystal structure of the complex can then be determined by the usual techniques. The interactions of inhibitors and pseudo-substrates with crystalline enzymes have been

studied in this way[1,2]. Until now, however, it has not been possible to use this approach to study the binding of an actual substrate, because collection of a full set of three-dimensional X-ray diffraction data at high resolution takes at least several days, while the lifetime of a productive enzyme–substrate complex, even in the crystalline state, is several seconds or less. Thus, averaged over the time of data collection, the observed structure will contain only a negligible amount of enzyme–substrate complex.

The structure of a productive enzyme–substrate complex or an intermediate on the catalytic pathway could be determined crystallographically if the rate of enzyme catalysis could be reduced considerably. Douzou has pointed out that this can be done by lowering the temperature[3]. The Arrhenius equation relating reaction rates to temperature predicts that an enzymatic reaction having an energy of activation of −15 kcalorie mol^{-1} will be slowed by a factor of 10^8 on cooling from room temperature to −100 °C. At this low temperature an enzyme–substrate complex with a lifetime of 10^{-3} s at +25 °C would be stable for 1.2 d. Douzou and his colleagues have made use of this effect to study some enzyme–substrate interactions in solution spectroscopically[4] and have also determined the physicochemical properties of many aqueous organic mixed solvent systems[5]. These solvents remain fluid at very low temperatures and, if their physicochemical parameters are properly adjusted, do not denature enzymes nor alter the rate-determining reaction step[6,7].

Recently Fink and his coworkers made a detailed study of the reactions of several serine proteases in both solution and crystalline states with ester and amide substrates in aqueous organic solvents at sub-zero temperatures[10,11]. They concluded that in carefully controlled conditions the enzymes would function normally in this bizarre environment but
Fig. 1 Plots of the changes in intensity with time of two high-resolution 0*kl* reflections of elastase as substrate is added. The solid curves are calculated assuming a first-order rate constant of $5.4 \times 10^{-5}\,\text{s}^{-1}$.

their rates were so reduced as to make direct observation of short lived proteolysis intermediates feasible. Fink has also determined conditions in which sufficiently high concentrations of such intermediates can be accumulated in crystals and has characterised the species formed[11]. These studies are invaluable for planning and interpreting X-ray diffraction experiments at low temperatures.

We have extended the techniques of cryoenzymology to protein crystallography by cooling protein crystals immersed in fluid mixed solvents, and then flowing in substrate at low temperature. In this paper we report the results of such an experiment with a specific synthetic substrate of porcine pancreatic elastase at −55 °C in 70% methanol–30% water *p*H* 5.2 (*p*H* denotes protonic activity in mixed solvents at the specified temperatures[5,11,13]).

Cryoprotection of elastase crystals

We chose a serine protease for our first experiments because there is a large body of kinetic and structural data available for this class of enzymes, but many details of their mode of action are still disputed[8]. They are also attractive because the rate-determining step in the reaction differs for different types of substrate. This offers the possibility of trapping several different intermediates crystallographically at low temperatures[10]. We chose elastase as the particular crystalline enzyme to study because of its low solubility and high stability in alcohol–water mixtures[11] and the very favourable molecular packing in its crystals. The active site of the enzyme faces a solvent-filled interstice 18 Å in diameter, allowing the binding of large peptide substrates[12].

Elastase crystals are grown from sodium sulphate–sodium acetate solutions at low ionic strength. They are normally stabilised in 1.2 M sodium sulphate, 0.01 M acetate (*p*H 5.0) and it was in this salt-rich mother liquor that the room temperature crystal structure was solved by Watson and his colleagues[12]. To cool the elastase crystals to temperatures in the −50 °C range (which we knew to be sufficiently low to stabilise an enzyme–substrate complex from the work of Fink and his colleagues[11]), it was first necessary to find a

replacement mother liquor which would not freeze[13].

We found that elastase crystals are stable in a wide variety of mixed solvents, provided certain procedures are followed. The crystals cannot be transferred directly from 1.2 M sodium sulphate to alcohol–water mixtures, because of the low solubility of sodium sulphate in alcohol. The first step of the transfer is therefore to place the crystals in 0.01 M sodium acetate (*p*H 5.0). In this salt-free liquid they are stable for weeks at 4 °C. Transfer cannot be made directly to solvents of high alcohol concentration, as this cracks and partially disorders the crystals. Transfer can safely be made, however, to solvents of low alcohol concentration, and the percentage of alcohol may be increased to any desired level provided the gradual addition of alcohol is coupled with a gradual reduction in temperature[13]. Alcohol concentration and temperature are varied so as to keep the dielectric constant of the solvent as near as possible to the value for pure water[4,13]. It is important at each step to vary the *p*H of the aqueous buffered component to keep the protonic activity of the solvent constant[4,13]. With this procedure alcohol concentrations from 10 to 80% can be reached with no damage to the crystals. Since a number of different solvents were available to us, we based our decision on the normality of kinetic behaviour of the enzyme in the solvent and its fluidity at low temperatures. Our choice was methanol–water (70%: 30%, v/v), a mixture of very low freezing point with a viscosity very close to pure water, even at −75 °C (ref. 5).

Data collection and substrate binding

To obtain stable enzyme–substrate complexes, the substrate must be flowed into the crystal at sub-zero temperature. Richards and his colleagues haved described a flow cell for use with single-crystal X-ray diffractometers that holds the crystal firmly in place while allowing liquid to flow through it continuously[14]. We have used this device both for substrate binding and solvent transfer experiments. In practice, the crystal is mounted in the flow cell in 0.01 M acetate (*p*H 5.0). It is then cooled to 5 °C on the diffractometer and the liquid is replaced by 20% methanol–80% water at the same protonic activity. The temperature is then lowered 10 °C and the liquid is replaced with one of 10% higher methanol concentration. It takes about 7 min for the wave front of fresh liquid to reach the crystal, and equilibration at each temperature/alcohol stage takes 10 to 15 min. For substrate binding at −55 °C a flow rate of about 2 ml d⁻¹ was used, with the substrate dissolved in 70% methanol and flowed over the crystal in the usual way.

Data were collected on a Syntex P2₁ diffractometer specially modified for protein crystallography (G.A.P. and D.T., unpublished), equipped with a Syntex LT-1 low temperature device which was also extensively modified (G.A.P., unpublished). Data collection was by Wyckoff step scan[14], which enabled us to collect 2,400 reflections per day. All low temperature work was done at −55° ±4 °C.

The substrate chosen for this study was *N*-carbobenzoxy-L-alanyl-*p*-nitrophenyl ester (ZAP), as this was the substrate about which the most kinetic information was available[11]. It was dissolved in 70% methanol, 0.01 M acetate (*p*H* 5.2) at 3×10^{-3} M. To avoid problems due to its spontaneous hydrolysis the solution was made fresh twice daily and kept at −35 °C.

The use of the diffractometer–flow cell system made it possible to follow the binding of ZAP crystallographically. A small set of medium intensity reflections at high resolution were monitored at regular intervals. Plots of their intensity with time were monotonic and could be interpreted in terms of a first-order process with an overall rate constant of $5.4 \pm 1.3 \times 10^{-5}\,\text{s}^{-1}$ (Fig. 1). This is in excellent agreement with the acylation rate constant measured for the ZAP–elastase crystal system at −50 °C by Ahmed and Fink[11], if the value is adjusted for the difference in substrate

Table 1 Refined heavy-atom parameters and phasing statistics

Derivative	Coordinates*			Occupancy†	Temperature factor A^2	Rc‡	$\langle f_H \rangle$§	E‖
	x	y	z

	0.1763	0.7747	0.0082	61	155.4			

*x, y and z are the heavy-atom coordinates in one asymmetric unit (one elastase molecule) in fractions of the unit cell edges.
†Occupancy in electrons on an approximate absolute scale.

‡Rc is the Cullis R-factor $\dfrac{\Sigma||(F_{PH}-F_P)|-f_H|}{\Sigma|(F_{PH}-F_P)|}$ the sums being over all centric reflections[19].

§$\langle f_H \rangle$ is the r.m.s. heavy-atom structure amplitude in electrons.
‖E is the r.m.s. lack of closure of the phase triangle at the most probable phase, in electrons[20].
The mean figure-of-merit[21] for the 2,981 reflections to 3.5 Å is 0.73.

concentration (we observed that the rate varied linearly with substrate concentration, as expected). Collection of a complete set of three-dimensional data to 3.5-Å resolution was begun after the binding curves had levelled off; two days were required to collect the set. Neither low temperature nor substrate binding caused any damage to the elastase crystals; indeed, the mosaic spread of the crystal decreasing by 25% on cooling. The unit cell parameters of the enzyme in alcohol at −55 °C and the enzyme–substrate complex at the same conditions agreed within 0.5% with those of the enzyme in water at room temperature ($a=51.5$ Å, $b=58.0$ Å, $c=75.5$ Å, $\alpha=\beta=\gamma=90°$, space group $P2_12_12$), suggesting that the three cases were mutually isomorphous.

Phase determination

The crystallographic binding curves suggested that substrate was binding to the crystalline enzyme at low temperature, but to interpret the binding, a set of phase angles for the native enzyme structure was required. Phases were available from the earlier room temperature structure determination[12], but we did not use them. The room temperature structure was of an inhibited enzyme; moreover, one of the heavy-atom derivatives used to solve the structure was itself a covalent inhibitor. The phase angles from this structure determination therefore might be biased towards the presence of material in the substrate binding site. We decided to obtain phase information free from possible
Fig. 2 Photographs of the active site region ($y = 10/60$ to $50/60$, $z = 10/60$ to $50/60$) of stacks of seven sections ($x = −13/60$ to $−7/60$) of the various electron density maps of elastase at low temperature. Phase angles derived for crystals at room temperature in sodium sulphate were used for all maps. For the difference maps the r.m.s. error in electron density was calculated from the revised Henderson and Moffat formula[18], and contours were drawn at intervals of this value, beginning at twice the error. Positive density is enclosed by solid contours, negative density by dashed lines. The ordinary electron density maps have been contoured at equal but arbitrary intervals of positive density; the interval was chosen to approximate that used by Watson *et al.* in Fig. 5 of ref. 12. *a*, Difference electron density map using as amplitudes F (elastase in methanol at −55 °C) −F (elastase in sodium sulphate at +25 °C). The spherical negative density is due to the replacement of a bound sulphate ion by acetate (T.A. and G.A.P., unpublished). The molecular boundary can be determined by reference to Fig. 2*b*. *b*, The amplitudes used in this map were $2F$ (elastase at −55 °C) −F (elastase at +25 °C). This gives a picture of the structure of the enzyme in methanol at −55 °C. Some of the important side chains in the active site are labelled. The black dot marks the position of the β-O of SER-195. (Compare with Fig. 5 of ref. 12.) *c*, Difference electron density map calculated with amplitudes F (elastase + ZAP at −55 °C) −F (elastase at −55 °C). The use of elastase in methanol at −55 °C as the parent structure in this difference map cancels out the high noise in the solvent region seen in Fig. 2*a*. *d*, The difference map of *c* superimposed on *b*, showing the interactions the substrate makes with the enzyme. The methyl group of the alanyl portion of the substrate points into the paper, where it is in contact with the methyl group of VAL-216.

bias by solving the structure of the uninhibited enzyme at 3.5-Å resolution using heavy-atom derivatives which do not bind in the substrate binding site. Two were quickly found, one of which, uranyl nitrate, was used in the earlier study[12]. All phase determination was done on the enzyme in 1.2 M sodium sulphate (pH 5.0) at +25 °C for reasons of speed and convenience. Details of the phasing will be published separately. Though not as high in quality as the earlier work, the phase determination was acceptable (Table 1). These phases for the uninhibited native enzyme in sodium sulphate were used for all electron density calculations.

Electron density maps

In addition to the room temperature data collected to phase the structure amplitudes, complete sets of data to 3.5-Å resolution were collected on elastase in 70% methanol at −55 °C and elastase + ZAP in 70% methanol at −55 °C. An electron density map of the native enzyme at +25 °C in sodium sulphate was virtually identical to that obtained by Watson and colleagues on the inhibited enzyme[12]. The only significant differences were the absence of the inhibitor density, the presence of a dense spherical feature in the active site interpreted as a bound sulphate ion[15], and the repositioning of HIS-57 to form a complete charge-relay system identical to that observed in chymotrypsin[16] (the histidine is prevented from assuming this position when the inhibitor is bound).

Two electron density maps were calculated for native elastase in methanol at −55 °C. The first, a difference electron density map between the low temperature and room temperature crystals, has as its largest feature a hole at the position of the bound sulphate ion, indicating that this ion is lost in the salt-free mixed solvent, as expected (Fig. 2a). There are no significant features within the molecular envelope, although there are numerous peaks and holes in the solvent-filled interstice. The only significant positive features are on the surface of the molecule, and we have interpreted these in some cases as slight shifts in the position of side chains, in others as the appearance of side-chain density where none was visible at room temperature (presumably because of thermal vibration). The second map shows the electron density of elastase in 70% methanol at −55 °C. The positions of important amino acids in the active site region were noted in this map (Fig. 2b).

We next calculated a difference Fourier synthesis which showed the difference in electron density between elastase and elastase + ZAP, both in 70% methanol at −55 °C. The only significant feature was a bilobed peak in the active site region (Fig. 2c). One of the lobes was within covalent bond distance from the β-oxygen of SER-195; the other, a planar density feature, was interpreted as the benzene ring of the carbobenzoxy group. There was no density for the p-nitrophenol portion of the substrate. An integrated electron count of the peak indicated approximately 80% occupancy for the substrate, in excellent agreement with the value found by Fink and Ahmed[11]. When this difference map was superimposed on the electron density map of the unsubstituted enzyme at −55 °C, the close contact with SER-195 was obvious (Fig. 2d; the black dot in the centre of the photograph is the β-oxygen position as determined by Watson and his colleagues at 2.5-Å resolution[17]). We interpret these maps as depicting a stable, productive acyl-enzyme intermediate in the catalytic process, as predicted by Fink and Ahmed in the accompanying article[11]. We believe that the substrate was bound to the crystalline enzyme, that p-nitrophenol was split off when the alanyl residue became covalently attached to the β-oxygen of SER-195, and that deacylation was prevented from occurring by the low temperature used in the study. To test this interpretation, we attempted to wash the crystal free of bound substrate at −55 °C. After 4 d of continuous flow of substrate-free 70% methanol a set of data was collected

and another difference Fourier synthesis was calculated. The results showed no reduction in the amount of bound substrate, suggesting that the mode of attachment was covalent. When the temperature was raised to −10 °C, the intensity binding curves reversed, suggesting loss of bound substrate. Another set of data was collected after 20 h at the elevated temperature, and this showed no detectable substrate remaining in the active site.

Low temperature protein crystallography

We do not believe it is appropriate, at this stage of the analysis with its modest resolution, to use these results to answer detailed questions about the mechanism of serine protease catalysis or the nature of the catalytic power of enzymes. We hope that some insights into these questions will come from the extension of this work to much higher resolution and several different substrates. For example, since the rate-limiting step for the hydrolysis of p-nitro-anilide substrates is the formation of the acyl enzyme rather than its breakdown, binding a substrate of this type to the crystalline enzyme at low temperature may yield a pre-acyl enzyme intermediate or the Michaelis complex[11]. This would give a second "stop-action" photograph of a different point in the overall reaction pathway. Our present study, combined with the work of Fink and Ahmed in the accompanying article[11], which was essential for the planning and interpretation of our experiments, demonstrates that it is feasible to use low temperature protein crystallography to stabilise and study actual enzyme–substrate complexes. We believe that the technique has great potential to reveal the atomic details of enzyme catalysis, especially when it can be applied to several substrates with different rate-determining steps. In conjunction with kinetic and spectro-scopic studies of crystalline and dissolved enzymes[22,26], this technique offers the hope of increased understanding of the events in the catalysis of reactions by enzymes. We believe that cryoenzymology can be applied to a wide variety of crystalliseable enzymes.

letters to nature

Do freely falling bodies radiate?

IT seems clear that, although gravitational radiation has not yet been detected, its existence is predicted by general relativity. Whether freely falling bodies, that is, bodies moving under gravitation alone, radiate gravitational waves is, however, quite unclear. This is an important question because most astronomical motion is free fall, and if radiation is not produced by this, there will be much less of it present than some investigators believe. The situation has been clearly explained by Ehlers, Rosenblum, Goldberg and Havas (unpublished). Briefly, the doubts arise because those approximation methods which quite convincingly predict gravitational radiation from certain moving systems do not apply to bodies in free fall.

The question could be answered by suitable exact solutions of Einstein's equations. Until recently, however, the known exact solutions for freely falling matter have been spherically, plane or cylindrically symmetric or have been homogeneous: that is, they have had too much symmetry to be realistic models for radiating systems.

An exact solution has now been discovered[1] which is sufficiently unsymmetric to throw important light on the subject. It is a solution of Einstein's equations for dust, which is, of course, matter under no forces except gravity. The metric is

$$ds^2 = -e^{\lambda}dr^2 - e^{\omega}(dy^2 + dz^2) + dt^2 \qquad (1)$$

where

$$e^{\frac{1}{2}\omega} = \frac{\varphi(r,t)}{P(r,y,z)}; \quad e^{\frac{1}{2}\lambda} = \frac{P}{W(r)}\frac{\partial}{\partial r}e^{\frac{1}{2}\omega} \qquad (2)$$

$$P = a(r)(y^2 + z^2) + 2f(r)y + 2g(r)z + c(r) \qquad (3)$$

$$ac - f^2 - g^2 = \tfrac{1}{4} \qquad (4)$$

φ is a Friedmann function, that is, it satisfies the Friedmann equation

$$\dot{\varphi}^2 = [W(r)]^2 - 1 + \varphi^{-1}S(r) \qquad (5)$$

where the dot means $\partial/\partial t$; a, f, g, c, W, S are arbitrary subject to equation (4), and a further arbitrary function arises in the integration of equation (5). The density ρ is given by

$$8\pi\rho = \frac{PS' - 3SP'}{\varphi^2(P\varphi' - P'\varphi)} \qquad (6)$$

where the prime means $\partial/\partial r$. By a suitable choice of arbitrary functions the density may be made positive everywhere; and it can also be made to fall off with r as rapidly as one likes, so the solution may be thought of as referring to a cloud of dust concentrated towards the centre but extending very tenuously to infinity.

The motion of the dust, governed by equation (5), is one of expansion or collapse, as in the Friedmann cosmological models, but dependent on the radial coordinate r. The two-dimensional surfaces r = constant, t = constant are spheres and y, z are stereographic coordinates. The spheres of different radii are not concentric, however, and taken as a whole the three-dimensional space of r, y and z is not spherically symmetrical. In fact the solution has no Killing vectors whatever for general values of the arbitrary functions (W. B. B., A. H. Sulaiman and N. Tomimura, unpublished).

Does the space–time contain gravitational radiation? It is not easy to answer this question: there is no conclusive mathematical test for the presence of radiation in a space–time, and to examine the solution for a radiative flux at spatial infinity turns out to be difficult because of the comoving coordinate system in which the solution is formulated. The following argument seems conclusive, however, Consider the portion of the solution (1)–(6) contained within $0 \leqslant r < r_0$ (r_0 = constant). I have shown (unpublished) that it is possible to match this portion to a Schwarzschild metric which is valid for $r > r_0$. The Schwarzschild metric being static there is no radiation passing through it, so the moving dust in the region $0 \leqslant r < r_0$ is not radiating.

It would be quite wrong to argue from this that freely falling matter never radiates. The investigation does, however, show the existence of a class of non-radiative motions of dust in a space–time without Killing vector symmetries.

Globular clusters as a source of X-ray emission from the neighbourhood of M87

AT least five galactic X-ray sources have been identified with globular clusters[1-3], and it is possible that a similar association holds for the bright unidentified sources near the galactic centre[4]. Intense X-ray bursts have been detected[5] from the direction of one of these (3U1820−30/NGC 6624), and a star cluster, probably globular, has been found[6] in the error box[7,8] of the so-called 'rapid burster', MXB1730−335. Moreover, the error box of a hard X-ray flare observed from the Cosmos 428 satellite[9] contains NGC5904 (M5). This globular cluster has similar properties[10] to the others that emit X rays, and if normally weak it is unlikely to have appeared in the Uhuru catalogue because of its position. The X-ray emission from globular clusters may be attributable to accretion on to compact objects, the accreting material being supplied from binary companions[11-14], or gas trapped in the potential well of the cluster[15,16].

There are relatively few intrinsically bright optically observed globular clusters in our Galaxy. Counts of objects in the vicinity of M87, however, reveal that it has an extensive halo of globular clusters[17,18], the number of which may exceed 10,000 within a radius of 23 arc min (ref. 19). The greater number of bright globular clusters in M87 may be explicable as a population effect[18]. The similarities

between the optical properties of these globular clusters and those in our own Galaxy suggest that the former may also contain X-ray sources.

The brighter globular clusters in M87 may also be substantially more X-ray luminous. The presence of a massive black hole or of captured binaries depends sensitively on the properties and past history of the core of the globular cluster. Gas to fuel a massive black hole, or single neutron stars, in a globular cluster orbiting our Galaxy will be stripped on passing through the galactic disk, and possibly even through the halo[20]. This stripping will not occur in an elliptical galaxy; consequently, there may be proportionally more gas available in identical globular clusters in M87 than in our Galaxy.

On either hypothesis, the average X-ray luminosity of individual globular clusters may be of the order of 10^{38} erg s^{-1}. This raises the possibility that the integrated globular cluster emission may account for a substantial fraction of the X-ray emission observed from the region of M87 ($L_X \sim 7 \times 10^{42}$ erg s^{-1}; ref. 21). (Katz[22] has suggested that the X-ray emission from clusters of galaxies may be attributable to unspecified compact sources.) In support of this proposition we note that the extended X-ray emission[21,23] from the Virgo cluster is centred on M87, which lies ~45 arc min from the cluster centroid. We expect that the general X-ray emission from the globular cluster will appear to be smoothly and symmetrically distributed about M87 at moderate spatial resolution. A few clusters of higher luminosity might be resolvable with currently proposed imaging X-ray telescopes.

A similar situation may apply to the elliptical galaxy NGC3311 in Abell 1060, which as a cluster has been suggested as the identification for the X-ray source 3U1044−30[1,24]. It seems possible that that galaxy is surrounded by a similar globular cluster population to that of M87 (ref. 25).

We thank Dr David Hanes for valuable discussions.

Pre-terrestrial shear faulting and heat treatment of the Jamestown iron meteorite

WE have made a metallographic examination of a 250-g slice of the Jamestown iron meteorite. The meteorite was first reported by Huntington[1] as a mass of 4 kg, with a dished,

flake-like shape of maximum dimensions $26 \times 13 \times 3.7$ cm, and with two entirely different external surfaces—a smooth convex side, and a slaggy, vesicular, concave side, pitted by circular cavities up to 2 cm in diameter. Buchwald[2] has reported on the general metallography of the Jamestown Iron but does not record which of the many sections of this meteorite his description is based on.

Our British Museum specimen (BM 67215) mates with that shown in Fig. 3 of ref. 1. Most of our general microscopic observations are in agreement with those of Buchwald[2]. We found that phosphide is absent, daubreelite is present as rare particles, and troilite is present in varying degrees of shock alteration. The size and shape of the ε-kamacite, taenite and plessite components are consistent with membership of chemical group IVA in the classification scheme of iron meteorites.

Furthermore, the convex surface of the British Museum specimen retains relics of a heat alteration zone, produced by ablative burning during atmospheric entry. The concave surface shows somewhat less penetration of heat alteration but instead shows a considerable accumulation of the products of ablation melting, which Buchwald[2] describes as fine grained metallic eutectics. The Jamestown meteorite must have traversed the Earth's atmosphere as an oriented projectile with the convex surface leading.

The surface heat alteration overlies all other aspects of metallic macro- and microstructure which must therefore be of pre-terrestrial origin and not produced by impact with the surface of the Earth. Buchwald[2] has noted that the ε-kamacite must have been reheated. Though it is not easy to specify the exact conditions of heat treatment, some limits may be proposed, since on low power examination the kamacite seems to consist of the acicular ε structure noted by Jain and Lipschutz[3], but our examination at higher magnification shows that the ε within the bulk of the kamacite is diffused but not recrystallised. This absence of recrystallisation in the bulk of the kamacite suggests a reheating temperature below 450 °C, since our laboratory heat treatment of the shock-hardened kamacite of Trenton does show detectable recrystallisation at this temperature.

Buchwald[2] noted local distortion, shearing and folding of plessite and taenite, but did not indicate the scale of these effects and did not examine the detailed metallography of the shearing, which in some instances is encountered on a macroscopic, not a local, scale. Indeed, the outstanding feature of the etched macrostructure of the British Museum specimen is the interruption to the regularity of the Widmanstätten pattern by the traces of at least five shear-displacement surfaces, of which the longest extends for 6 cm and leaves the meteorite at two points on the leading convex edge. Others extend from the trailing concave surface inwards for about 2 cm. One of the latter has developed into the shear-displacement type of crack that Axon and Steele-Perkins[4] have reported in fragments of the Henbury Iron. It is, however, important to recognise that the shear-displacements in the Henbury specimen were produced by the crater-forming impact of the meteorite with the Earth's surface; but the shear-displacement crack in the Jamestown Iron is invaded by ablation melt product and is therefore of pre-terrestrial origin.

Attention has been directed to the absence of recrystallation in the bulk of the ε-kamacite, and a reheating temperature < 450 °C deduced. By contrast, the more heavily deformed material within and immediately adjacent to the surfaces of shear displacement in the Jamestown Iron has recrystallised. The zones of finely recrystallised kamacite extend on both sides of the shear surface to a width of about 0.15 mm, and it is this band of recrystallisation that accentuates the appearance of shear surfaces in the macrostructure. This local recrystallisation of the heavily sheared material is consistent with the proposed reheating temperature, and explains why the macroscopically visible thickness of the shear traces (~ 0.15 mm) in the Jamestown Iron is greater than in other meteorites previously examined by us.

The metallographic features of the Jamestown meteorite would be consistent with the following history. After a period of slow cooling (approximately 300 °C Myr^{-1}, according to the bandwidths reported by Buchwald[2]) in which the Widmanstätten structure developed, the material formed part of a massive projectile that impacted, and formed a crater on, some unknown planetismal in the Solar System. The present Jamestown meteorite is part of a fragment that was produced during that crater-forming event. It shows shear displacement surfaces and the development of fracture by separation along the surfaces of shear faults in a manner similar to that noted by Axon and Steel-Perkins[4] for the terrestrial impact of the Henbury Iron. After the crater-forming impact the Jamestown material was heated to a temperature below 450 °C, probably by a blanket of hot ejecta on the surface of the unknown planetismal. At some later stage it was released from its intermediate host, circulated in space and eventually entered the Earth's atmosphere, where it acquired its heat alteration zone and an accumulation of ablation deposit, some of which penetrated a pre-existing shear fissure on the rear surface of the oriented projectile.

Shock effects are common in group IVA irons, and Jain and Lipschutz[3] have noted the presence of reheating effects after shock in the Boogaldi, Western Arkansas, Huizopa, Charlotte, Yanhuitlan, Maria Elena and Social Circle meteorites. The massive shear traces in the Jamestown Iron are, however, so far unique within the group IVA irons, although the Seneca Township meteorite shows a similarly diffused ε structure in its bulk.

We thank John Wasson, who provided early copies of ref. 2.

Lead and radium in the lower stratosphere

More than a decade ago Junge[1] found that the concentration of particles in the stratosphere is greater than in the upper troposphere, and that their main chemical constituents were ammonium and sodium sulphates, thought to arise from the ascent of their volatile precursors H_2S and SO_2 (ref. 2). In addition, minute concentrations of aluminium, calcium, chlorine, chromium, cobalt, copper, gold, iron, manganese, silicon and titanium have been detected[3,4], which, having no volatile precursors, enter the stratosphere as particles. As the extraterrestrial fraction in stratospheric aerosols is extremely small[5], their main source seems to be the surface of the Earth, but data available on the nature of such sources, and on the chemical composition and concentration of stratospheric aerosols are rather scarce—an astonishing fact, in view of their possible climatic impact. With this in mind, we have measured the concentrations of stable lead, ^{226}Ra and its radioactive daughter ^{210}Pb at various heights. These substances enter the atmosphere from several surface sources, both natural and artificial[6]. The concentration of ^{226}Ra in particulate materials such as soil dust or fly ash is well known, and may be used for the assessment of the stratospheric content of this kind of dust.

During the past three years we collected 112 samples of
Fig. 1 Vertical distribution of ^{226}Ra (– – – –) and stable Pb (—) in the atmosphere.

aerosols over Poland, from heights of 6, 8, 10 and 12 km. At each altitude 9–15 samples were collected in 1973, 6–9 in 1974 and 6–11 samples in 1975. The levels of the tropopause for each sampling profile were determined from data on the vertical gradient of temperature, supplied by the Institute of Hydrometeorology, Warsaw.

We used 1,600-cm^2 PVC fibre filters, type FPP-15-1.7 (Soviet made), placed in collectors suspended under the wings of LIM-type jet planes. After wet-ashing and dissolving the filters, the quantities of ^{226}Ra, stable Pb, ^{210}Pb, ^{90}Sr and ^{137}Cs collected were determined, using methods described elsewhere[7].

In Fig. 1 we present the annual mean air concentrations of stable Pb and ^{226}Ra, found between July and November 1973, May and October 1974 and March and December 1975. The striking feature is the high concentration (comparable with ground level) of ^{226}Ra and stable Pb at 12 km. In 1973 the mean ^{226}Ra concentration at 12 km was 0.7×10^{-4} pCi m^{-3} STP, 1.6×10^{-4} pCi m^{-3} STP in 1974 and 3.5×10^{-4} pCi m^{-3} STP in 1975. The mean stratospheric stable-Pb concentrations were 29×10^{-2} µg m^{-3} STP in 1973 and 1974 and 55.7×10^{-2} µg m^{-3} STP in 1975. The concentrations of ^{226}Ra which we found in Warsaw in the air at ground level range from 1.5×10^{-4} to 6.0×10^{-4} pCi m^{-3} and with the mean stable-Pb concentration of 10.0×10^{-2} µg m^{-3} in non-urban air[8].

Comparing Figs 1 and 2, it is also interesting to note that the vertical gradients of ^{226}Ra and stable-Pb concentrations in the troposphere are opposite to the gradients of the fission products. The concentrations of ^{226}Ra and Pb decrease with altitude between 6 and 10 km, reaching minima below the tropopause, and increasing sharply above it. This shows the ground level origin of these substances, and indicates the existence of trapping in the stratosphere.

Stable Pb, ^{226}Ra and ^{210}Pb have been discharged into the atmosphere by natural sources since time immemorial. Volcanic activity, forest fires and the action of the wind on soil and sea water are estimated to contribute ~ 5.4×10^{-4} µg of Pb m^{-3} of atmospheric air[9] and 3×10^{-9} pCi m^{-3} of ^{226}Ra (ref. 6). But the present concentrations of stable Pb and ^{226}Ra in the stratosphere are 2–3 and 5 orders of magnitude higher than these estimated natural levels. It follows that the bulk of
Fig. 2 Vertical distribution of ^{210}Pb (—), ^{137}Cs (- - - -) and ^{90}Sr (· · · · ·) in the atmosphere.

these nuclides in the stratosphere is probably of artificial origin, unless the estimation of their natural input is wrong. Coal burning, phosphate fertilisers and cement production are the main man-made sources of ^{226}Ra in the atmosphere; their global contributions have been calculated as 150, 400 and 1.8 Ci yr^{-1} respectively[6].

If the mean concentration of ^{226}Ra in the $\sim 10^{19}$ m^3 of atmosphere up to 20 km, were similar to that found in the lower stratosphere, that is $\sim 1.0 \times 10^{-4}$ pCi m^{-3}, then the total content of ^{226}Ra in this volume would be $\sim 1,000$ Ci, a value not much different than the annual contribution from artificial sources.

The main artificial sources of stable Pb are the combustion of lead alkyls in petrol, which contributes 120,000 t yr^{-1} (Northern Hemisphere)[10] and the burning of coal, contributing 3,000 t yr^{-1} (whole world)[8]. For the same volume of atmosphere, with a mean Pb concentration of 1.0×10^{-2} μg m^{-3}, the total lead content would be 100,000 t. These tentative calculations support the suggestion that most of ^{226}Ra and Pb in the stratosphere is of artificial origin.

During the years 1973 and 1974 a series of Chinese and French nuclear explosions has been conducted in the atmosphere, which is responsible for the increase of ^{137}Cs and ^{90}Sr in our samples in 1974 and 1975. It is interesting to see in Fig. 2 that ^{210}Pb concentrations in 1974 increased in parallel with those of fission products. In the first half of 1975, ^{210}Pb concentrations increased above the 1974 level, whereas a substantial decrease of ^{137}Cs and ^{90}Sr was observed. At the same time we found a sharp increase in the stable Pb content in both troposphere and stratosphere, seeming to suggest a common source for both types of lead. This is, however, improbable, as the specific activity of lead collected by us in the lower stratosphere is extremely high, reaching, in 1975, $\sim 330,000$ pCi ^{210}Pb per g stable lead, and, in 1974, $\sim 2,400,000$ pCi g^{-1}, 3–6 orders of magnitude above the specific activities of contemporary common lead, which range from 1.5 to 501 pCi g^{-1}

(ref. 12). This indicates that common Pb in the atmosphere is of no importance as a source of ^{210}Pb.

From the known concentrations of ^{226}Ra and stable Pb in coal[8,13], one can infer that the specific activity of lead in coal is $\sim 30,000$ pCi per g lead. In soil this specific activity is 15,000 pCi per g lead[11]. It follows that although coal and soil might contribute to stratospheric load of ^{210}Pb, the bulk of it comes from other sources. Coal burning contributes yearly ~ 200 Ci, and phosphate fertilisers 150 Ci (ref. 6). Natural production of ^{210}Pb in the atmosphere from ^{222}Rn, estimated as ~ 0.62 MCi yr^{-1} (ref. 12), clearly overwhelms these sources. Nuclear explosions are suggested to have produced fractions of a MCi of ^{210}Pb during the 1958–59 and 1961–62 test series, by the reaction ^{208}Pb(2n,γ)^{210}Pb, from the lead content of the construction of bombs[14,15]. This contribution, being transient and of short duration, would explain the excess peak concentrations of ^{210}Pb in the stratosphere accompanied by high concentrations of fission products as observed by us and others (P. W. Krey, unpublished). It also explains similar correlations found in fossil ice collected at glaciers in the Tatra Mts, Poland, the Jotunheimen Mts, Norway and the Himalayas, Nepal[11].

The minute industrial sources of ^{210}Pb, cited above, may locally influence the content of this nuclide in air and precipitation, as suggested by several authors[6,14,16]. But the contributions from nuclear explosions, could affect the ^{210}Pb concentration on a global scale. This restricts the use of ^{210}Pb as a tracer in determinations of the age of glacier ice and in atmospheric transport studies.

If the ^{226}Ra content in stratospheric particulates were the same as in the fly ash or soil, ~ 1–5 pCi g^{-1} (ref. 11), then the 1975 concentration of mineral matter bound to ^{226}Ra would reach 50–250 μg m^{-3} STP in stratospheric air, at a height of 12 km. This is a rather high concentration. Were these particulates of artificial origin, it would imply that their accumulation in the stratosphere is a fairly new process, which if continued indefinitely might have an important climatic impact in the future.

This work has been carried out under the auspices of the US Environmental Protection Agency.

Progressive faunal migration across the Iapetus Ocean

DURING the Lower Palaeozoic, there was a gradual increase in the similarity of the faunas between North America to the west of the Appalachians, western Newfoundland, northwestern Ireland and Scotland on the one hand, and coastal
Fig. 1 The times at which faunas became common to both sides of the Lower Palaeozoic Iapetus Ocean. *a*, Closure of ocean (Norway); *b*, freshwater fish; *c*, benthic ostracods; *d*, trilobite and brachiopod species; *e*, trilobite and brachiopod genera (? island hopping); *f*, *Didymograptus bifidus*; *g*, *Dictyonema*.

New England, southern New Brunswick, Nova Scotia, eastern Newfoundland, England and northern Europe on the other hand. The best explanation for this is that the Iapetus (or Proto-Atlantic) Ocean was wide enough to separate two faunal provinces in Cambrian times, and that there was progressive migration of the more mobile components of the faunas as the old ocean closed (Fig. 1). The pelagic animals crossed first, followed later by animals (trilobites and brachiopods) with pelagic larval stages; but animals without a pelagic larval stage (such as benthic ostracods) were not able to cross until the ocean had closed at one point, though not necessarily everywhere along its length. Finally, faunas limited to fresh water or brackish water (like many Devonian fish) did not cross until there were non-marine connections between the continents on either side of the closing ocean.

Pelagic graptolites were among the earliest animals to appear on both sides of the ocean. The many-branched *Dictyonema flabelliforme* migrated across in the Tremadoc; but it was not until the Llanvirn (towards the end of the early Ordovician) that most other graptolites became similar on both sides. The two-branched *Didymograptus bifidus*, for example, appears in the Arenig of Texas, but did not reach England and Wales until the Llanvirn[1].

The next groups of animals to cross were those with pelagic larval stages, notably brachiopods and trilobites. Most genera in these groups were confined to one or other side of the Iapetus Ocean during the Cambrian and early Ordovician; the few cases where genera characteristic of different faunal provinces occurred together (including New World Island, Newfoundland) have been interpreted[2] as sites of oceanic islands colonised by sporadic spatfalls, which became centres of evolution and migration. The late Ordovician (Caradoc) brachiopod and trilobite faunas show less marked distinctions[3,4]; though most species are distinct, many genera are common to both sides of the ocean. It is not until the latest Ordovician (latest Ashgill; post-Richmond) that most species of brachiopods and trilobites became identical in Europe and America.

The specific distinctions in the Caradoc and early Ashgill indicate that, at its narrowest point, the Iapetus Ocean must have still been wide enough to prevent free crossing by most trilobite and brachiopod larvae. There are two quite distinct ways of measuring the width of the ocean at this time: by analogy with modern pelagic larva, and by analogy with modern rates of subduction.

Most modern brachiopod larvae have a pelagic stage of less than one week, though it may be as long as three weeks[5], and 80% of decapod larvae have ranges of between 2 and 7 weeks[6]. But benthic marine invertebrates commonly have a much longer larval life in the tropics, (for example, 7 to 43 weeks for tropical gastropods[7]). Britain and eastern Canada were at about 20°–35°S during the late Ordovician[8], so we conclude that the late Ordovician brachiopod and trilobite larvae (which seem to have crossed the Iapetus Ocean more or less simultaneously) may have had a larval duration of about 7 to 14 weeks. Data from Thorson[6] and Scheltema[7] suggest that larvae with this lifespan could possibly travel across an ocean between 2,000 and 4,000 km wide.

We have estimated that subduction occurred to the north of the Iapetus Ocean (in Scotland and north-western Ireland) between 530 (the age of the Oughterard granite of County Galway) and 390 Myr ago (the Glencoe Caldera of Scotland), a duration of 140 Myr; southward subduction occurred between 490 Myr ago (the Borrowdale Volcanics of northern England) and 440 Myr ago (the Mendip Hills and the Skomer Volcanics). If the average subduction rate during these periods was 4 cm yr^{-1}, then some 7,600 km of ocean crust may have been subducted between the late Cambrian and mid Silurian. Of this, some 4,800 km would have been subducted before the late Ashgill; thus, some 2,800 km of ocean crust might have existed in the late Ashgill. This argument assumes that an active spreading centre no longer existed in the late Ashgillian Iapetus Ocean; if it did exist the ocean could have been narrower. The estimates from pelagic larval migration and from subduction rates thus both suggest that the ocean had a minimum width of around 2,000–3,000 km during the late Ashgill.

The Iapetus Ocean probably did not have parallel margins; there is some evidence to suggest that it may have been wider in eastern Canada and the northern Appalachians than in Europe. The first closure occurred in the north-east[9], when Greenland and the Baltic Shield collided during the late Silurian. This date is supported by evidence from freshwater fish : the first recorded species to cross the Iapetus Ocean did so between Scotland and Norway during Wenlock or Ludlow times[10].

Subduction of ocean floor continued through the Silurian and early Devonian in the region between Britain and the northern Appalachians, and continental collision in this region (as opposed to Greenland and Norway) did not take place until after a large proportion of the Lower Devonian rocks had formed. The time of collision in this area is clearly related to the Acadian Orogeny, which can be dated as middle Emsian, that is, towards the end of early Devonian time[11].

Chronological evolution of the Kerguelen Islands syenite–granite ring complex

ALKALINE syenites in the Rallier-du-Baty peninsula of the Kerguelen Islands[1,2] intrude and metamorphose the basaltic lava flows which constitute the major part of the islands[3]. Recent work[4] has revealed the existence, in the peninsula, of five ring complexes consisting mainly of syenites containing from 2 to 15% normative quartz (Figs 1 and 2). The southern complex is the largest, and consists of nordmarkites (ring dykes *a, b, c*) and of quartz-rich syenites and alkaline granite (ring dykes *d, e, f*). Some minor intrusive bodies of gabbros (G) and nordmarkites (Σ) are located on the margins of the southern centre (Fig. 2). Chilled margins and enclaves in each individual ring dyke clearly indicate that the sequence of intrusions is centripetal. Furthermore, the contact relationships between the centres show that the magmatic activity has migrated northwards. Previous K–Ar data[5] have indicated that a syenite from the southern ring complex was emplaced 8.7 ± 0.9 Myr ago, whereas basaltic flows were erupted during the late Oligocene. An additional K–Ar age of 11.5 ± 0.2 Myr was obtained for a
Fig. 1 Location map of the Rallier-du-Baty peninsula (RB) in the Kerguelen Islands.

metabasalt collected near the contact with the syenites and was interpreted[3] as the minimum value for the time of eruption of the basalts.

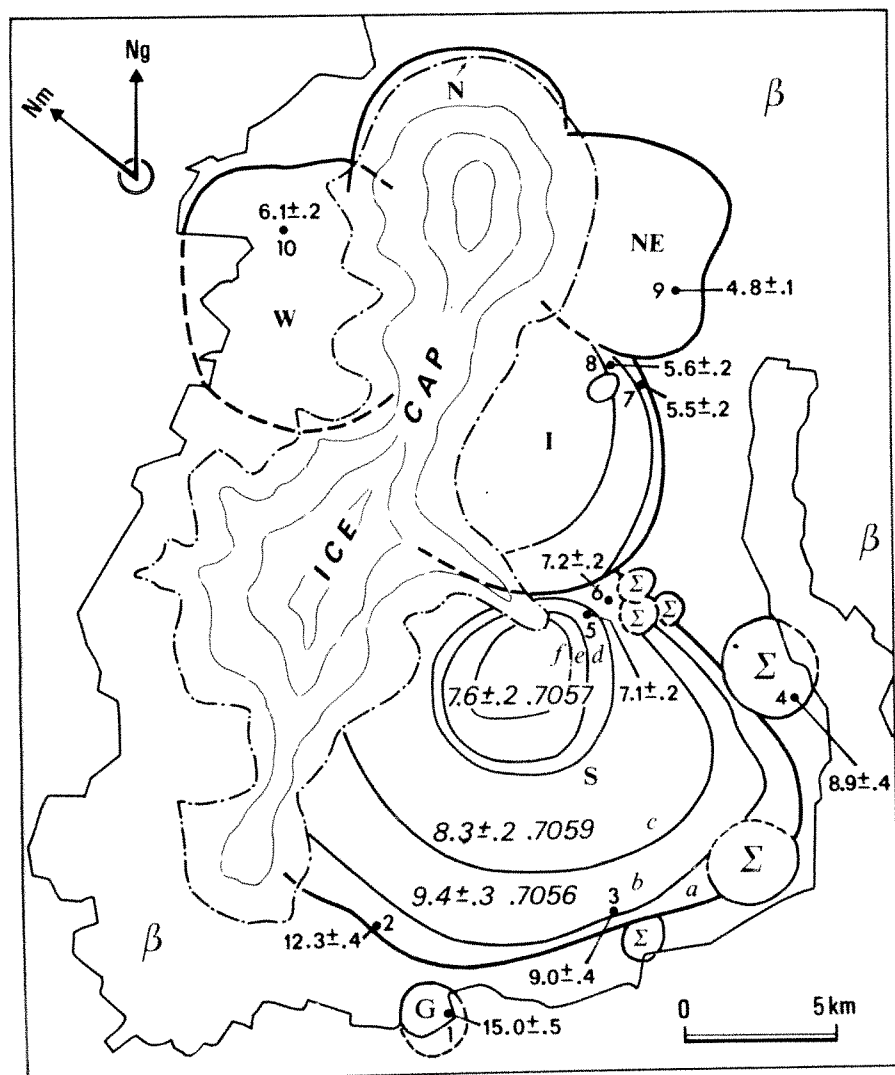
Using both K–Ar and Rb–Sr geochronological techniques, we have dated a series of samples, carefully selected from


Fig. 2 Geological sketch map of the Rallier-du-Baty peninsula, K–Ar (J.M.C.) and Rb–Sr (L.D., Ph.V.) results. S, Southern centre; I, middle centre; NE, north-eastern centre; N, northern centre; W, western centre. K–Ar results: 1, olivine gabbro; 2, quartz–syenite; 3, aplite dyke; 4, fayalite syenite; 5, granite (chilled margin); 6, microgabbro; 7, quartz–syenite (chilled margin); 8, microgabbro (dyke); 9, syenite; 10, biotite syenite. Rb–Sr results (see Fig. 3). Nm, Magnetic North; Ng, geographical North.

Fig. 3 *b*, Whole-rock isochron for syenitic ring dyke *b* (○), 9.4±0.3 Myr; *c*, whole-rock isochron for syenitic ring dyke *c* (●) 8.3±0.2 Myr; *d, e, f,* whole-rock isochron for granitic and syenitic inner ring dykes (▲), 7.6±0.2 Myr. I and II, Duplicate analyses on certain samples.
individual ring dykes in the southern centre (see Fig. 2 for sample localities) and have obtained the following results: (1) Both K–Ar and Rb–Sr methods yield consistent ages ranging from ∼ 15 Myr for the minor olivine–gabbro intrusion, and 12 Myr for the outer syenitic ring dyke, to ∼ 7 Myr for the inner ones and the core, with an interval of ∼ 1 Myr between the emplacement of adjacent ring dykes. (2) Most of the dated samples (Fig. 3) have very high Rb/Sr ratios (up to 300). Three whole-rock Rb–Sr isochrons yielded significantly different ages (9.4±0.3 Myr; 8.3±0.2 Myr; 7.6±0.2 Myr) but they all have very similar initial $^{87}Sr/^{86}Sr$ ratios. The 7.6±0.2 Myr isochron, however, combines various samples from the three inner distinct ring dykes (*d, e, f*) made up of alkaline granites and quartz syenites.

Some additional samples from the western, north-eastern, and intermediate centres have also been measured using the K–Ar method. The ages of the group of complexes range from > 12 Myr in the south, to < 5 Myr in the north-east. These data are in agreement with the deductions made from the field observations and suggest that the magmatic activity migrated at a very slow rate during the Upper Miocene.

The very high, yet variable, Rb/Sr ratios, as well as the radiogenic nature of the samples from the southern centre, allow a fairly precise whole-rock Rb–Sr isochron to be obtained for these very young rocks for the first time. The centripetal age distribution in the southern centre may reflect the consequence of a progressive cooling from the outer ring dyke to the core; however, the presence of chilled margins in the outer part of the ring dykes *a, b, c* and *d* (Fig. 2) practically rules out such a possibility. The whole-rock Rb–Sr ages are therefore interpreted as the individual times of crystallisation. The duration of about 5 Myr for the igneous activities in this ring complex is especially informative in terms of the formation of one complete ring complex. Although other similar ring complexes have already been studied in New Hampshire, Nigeria, Niger and Rhodesia[6–9], the actual time span for the development of igneous activity in a single ring complex could not be obtained because of the overlap of the analytical errors for the individual ages in successive intrusions.

The initial $^{87}Sr/^{86}Sr$ ratios for the three isochrons are: 0.7059±0.0003 for ring dyke *b*, 0.7056±0.0004 for ring dyke *c*, and 0.7057±0.0004 for all three inner ring dykes *d, e* and *f* and these values are in agreement with previous data[10,11]. Using Hedge's measurements, the calculated initial $^{87}Sr/^{86}Sr$ ratio is 0.7055 for three syenitic samples from the southern complex and one sample from a gabbroic intrusion of the Courbet peninsula. We suggest therefore, that the source regions for different ring dykes have the same Sr isotopic composition. Furthermore, the interval between the production of melt and the final crystallisation may have been very short (< 1 Myr in

this case), because, in our opinion, the very high Rb/Sr ratio could produce a very rapid increment in the $^{87}Sr/^{86}Sr$ ratio in the melt if fractional crystallisation was prolonged. The distinctly high initial $^{87}Sr/^{86}Sr$ ratios reported[7] in some geochemically similar rocks (Rb/Sr up to 1,200) from Nigeria which have previously been interpreted in terms of crustal contamination, may have an alternative interpretation if the liquids took a longer time to crystallise finally.

The question of whether continental crust or oceanic crust[10,11] exists beneath the Kerguelen Islands cannot be resolved from the Sr isotopic data alone. But neither do we have any geochemical or geological (xenolithic) evidence for the presence of continental material under the basalts.

Native copper in DSDP sediment cores from the Angola Basin

LEG 40 of the Deep Sea Drilling Project (DSDP) drilled two holes in the Angola Basin: site 364 and site 365 (Fig. 1). Native copper was found in two samples (364-5-2, 19–21 cm and 364-5-2, 22–24 cm) from one of the cores taken at site 364. The botryoidal form of most of the copper grains initially suggested formation *in situ* and the subsequent discovery of copper casts of planktonic foraminifera removed any lingering thoughts of contamination. This is not the first report of native copper in DSDP cores. Most other occurrences have, however, been found in basement rocks (for example, site 282) or in the sediments immediately overlying basement rocks (site 105), whence the copper was presumably derived. The copper reported here occurs at least 3 km above volcanic basement rocks, and no copper has yet been found in samples above or below it. Only at site 149 (Venezuelan Basin) has copper previously been found in non-basement-associated sediments. There it occurs as "a number of very small metallic incrustations" in one core of pelagic clay[1].

Site 364 was drilled in a water depth of 2,449 m (see Fig. 1). The copper rests in moderate yellowish brown (10YR 5/4) to light olive grey (5Y 5/3) Miocene marly nannofossil ooze at a depth of ~ 152 m below the sea floor. Native copper was found in only the samples mentioned, although all other samples at the writer's disposal from this site (364) and the adjacent site (365) were carefully re-examined after copper was found. The sample at 22–24 cm contained five grains of copper whereas the sample at 19–21 cm contained several dozen. My data refer only to the latter sample.

Native copper makes up 12% (by weight) of the total sample. The copper grains are metallic reddish-brown, mostly botryoidal masses, and individually range up to 4 mm across. A number of copper casts of planktonic foraminifera (Fig. 2) are also present (the frontispiece of vol XL, *Initial Reports of the Deep Sea Drilling Project* carries colour photographs of several of these grains). Many of the grains of copper are partially coated with very light green calcium carbonate and clay; most, but not all, of this coating is soluble in dilute HCl. The greenish tint is probably caused by reaction of the copper with the surrounding carbonate-rich sediments, forming copper carbonate.

Table 1 shows that, with the exception of small amounts of sulphur, the grains can be considered wholly copper (the concentrations of the other elements, if real, are negligible). The presence of 0.18% and 0.64% sulphur suggests a very small amount of copper sulphide may be present. The copper value in the < 89-μm diameter size fraction is obviously vastly higher than in normal marine sediments[1], indicating that minute copper particles are also present in this fine fraction. Concentrations of the other elements in this fraction are more or less normal for marine sediments.

The presence of native copper in any natural environment (whether igneous, metamorphic, or sedimentary) is always somewhat surprising in view of the ease with which copper combines with other elements (especially sulphur). Nevertheless, copper abundantly exists in this form in a diversity of environments, and the literature on the subject is voluminous. Its presence in sedimentary rocks, the concern of this study, is less common than in igneous rocks, but the literature is still extensive[2,3].

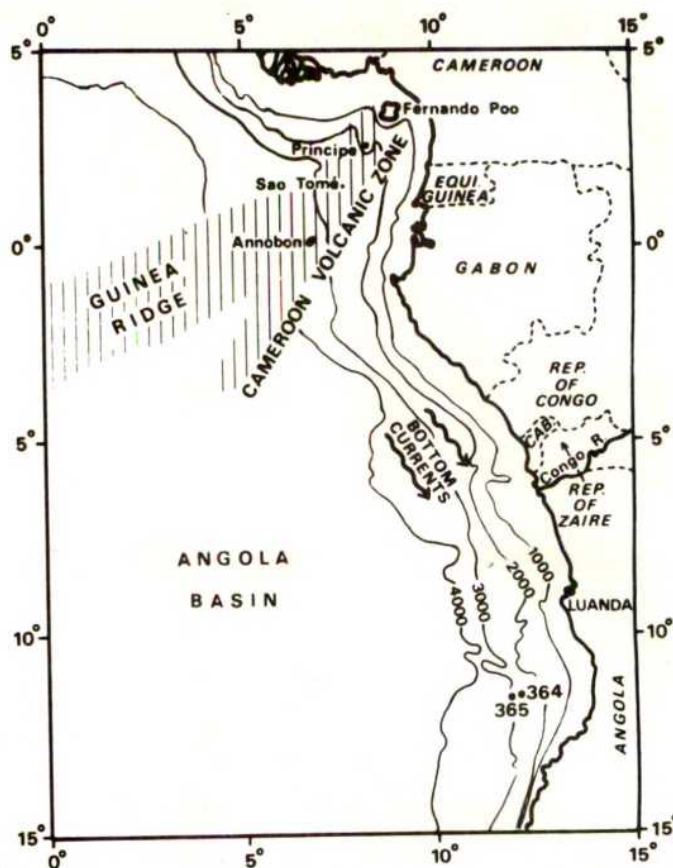
Onshore erosion and mechanical transport of these particles to site 364 may be discarded as a possible mechanism of origin. It is difficult to imagine transport which would bring only copper grains to this site, without other terrigenous grains as well. Moreover, the copper grains are not rounded and abraded, as would be caused by any transporting mechanism capable of carrying these large grains. Finally, the presence of copper-infilled planktonic foraminifera conclusively proves an *in situ* deposition from copper solutions.


Fig. 1 Location map after Emery *et al.*[16] showing site 364, where native copper has been found, and site 365. Isobaths in metres.

Syngenetic origin of copper in marine sediments requires: first, a source of the metal; second, transporting solutions and a force to move them and third, a precipitating agent. Several conceivable origins for the metal: a deep-seated magma, with ascending hydrothermal solutions carrying copper, extraction and concentration of copper from seawater by microorganisms, whose death causes localised enrichment of copper in the sediments (for example, the Kupferschiefer Formation[4–6]), or, finally, copper solutions derived from a submarine basaltic extrusion and transported to the site by currents.

Fig. 2 Electron microprobe scan showing homogeneous distribution of copper in a planktonic foraminifer cast. All light areas are copper; dark areas within the cast are unfilled spaces.
Several lines of sedimentological and chemical evidence militate against the first two possibilities', and the third possible source is the most attractive. This type of source has been described as "volcanic emanations" or "hydrothermal exhalations" by many authors. Geochemical evidence has been presented which would seem to prove the presence of submarine hydrothermal solutions⁸. The margins of hot, submarine-erupted basaltic rocks are quickly cooled, forming pillow structures whose chemistry approximates the chemistry of the erupted liquid. The slowly cooled interiors of the flows are, on the other hand, depleted in certain elements which are known to be enriched in pelagic sediments and manganese nodules⁸. This depletion is caused by seawater entering the eruptive flow through contraction fractures, being heated, and dissolving volatiles and metals concentrated in the residual phases within the interior of the extrusion. Metals are then mobilised as chloride complexes⁸. This is in accord with work showing that a Na–Ca–Cl brine is a potent solvent for copper and other metals⁸.

This heavy, metal-enriched brine could be expected to flow over the sea floor, directed by gravity, bottom currents, or both. It is tempting to consider the north-east–south-west trending Cameroon Volcanic Zone as the possible extrusive source. This volcanic zone extends almost 600 nautical miles off-shore, the terminal end being < 700 nautical miles north of site 364 (Fig. 1). Moreover, the offshore segment is known to have extruded basalt during the Miocene⁹. Present-day movement of bottom currents in the eastern Angola Basin is to the south¹⁰. If a similar circulation prevailed during the Miocene —and it is believed that Neogene current patterns were similar to those of today¹¹—transport of the brine to the site 364 area would have been the result.

No matter where a copper solution came from, or how it eventually reached site 364, some agency caused it to precipitate native copper. Organic matter has been suggested as a possible agent¹⁸,³. There have been several reports of native copper forming in modern peat swamps rich in organic matter¹¹⁻¹⁴. This is especially intriguing in view of the occurrence of authigenic marcasite at site 364 (ref. 15). Marcasite is a

mineral normally associated with peat swamps and is unusual in the marine environment. Its sporadic occurrence at site 364 suggests periodic conditions of extreme acidity. Bacteria may assist organic matter in precipitating native copper in acidic swamps. Indeed, metallic copper has been produced experimentally from copper solutions by using swamp bacteria¹⁸. Apparently native copper is formed by the reaction of bacterial waste products with copper solutions¹⁸ A concentration of organic matter may have been the precipitating agent at site 364, even though the sediments are not enriched in organic matter today.

Many questions still remain unanswered. Why, for example, are no other metals or their sulphides (other than pyrite) found at this horizon? Surely hot brine would have dissolved

other metals from basalt, if this were the source. Perhaps the fact that the common metals precipitate (as sulphides) in the order Cu, Zn, Pb, Ag may be relevant. Could copper have been precipitated here, early and alone, then the brine transported elsewhere to deposit other metals?

The foregoing discussion of the origin of this copper is highly speculative; it would be naive to think that a final and complete answer can be given yet. Nevertheless, it is hoped that the hypotheses presented will stimulate further ideas on the genesis of this unusual copper deposit.

I thank Mr R. S. Rickard for operating the microprobe and Professor R. V. Dingle and Mr J. H. W. Ward for helpful comments.

Experimental evidence that oxygen is the principal impurity in natural diamonds

IN virtually all treatments of the physical properties of natural diamonds, nitrogen is considered to be a major impurity and is used to explain many properties (see ref. 1). This is true because of the analysis of ref. 2 where a good correlation between nitrogen concentration and optical spectra was found. Those results were obtained from the conversion of diamonds to graphite in a carbon crucible. The report that nitrogen is the major impurity in type 1 diamonds can be tested indirectly and qualitatively by analysing occluded gases released by crushing such diamonds. Numerous experiments in this laboratory on diamonds from Africa, North and South America have failed to show that nitrogen is the major impurity in natural diamonds³,⁴ and we decided to reinvestigate the composition of gases released by the conversion to graphite of natural diamonds. We found oxygen and hydrogen to be the major impurities, and nitrogen to have only a minor role.

The diamonds used were both type I and type II (as characterised by ultraviolet absorption⁵), and free of detectable inclusions under binocular microscope examination at 90× Their body colour ranged from colourless to pale yellow and their weight ranged from 0.070 to 0.200 g. Possible contamination of the gases released from the surface of the apparatus was minimised by transforming the diamond crystals in a resistance-heated rhenium filament located near the centre of a large Nonex glass vacuum chamber. The vacuum chamber was attached to the inlet system of a research mass spectrometer⁷. Before being converted to graphite the diamond crystals were maintained at a temperature of 800 °C and a vacuum of 10⁻⁸ mmHg for several hours to remove possible surface contamination

Table 1 Analysis of gas released by the conversion under vacuum of a natural type I diamond (0.143 g) to graphite

Gas $T(°C)$	Percentage abundance (volume)						
	1,500	1,800	1,900	2,000	2,200	2,700	2,900
H_2	8.69	7.60	6.53	3.20	2.42	7.41	4.65
CH_4	0.46	0.22	0.27	0.16	0.26	0.27	0.14
H_2O	0.89	3.03	9.90	4.15	2.39	3.02	5.12
CO	78.98	87.12	79.57	90.67	90.88	84.68	86.09
N_2	1.05	0.86	0.90	0.78	0.82	0.73	0.79
Ar	0.03	0.02	0.02	0.02	0.02	0.01	0.02
CO_2	9.90	1.15	2.81	1.02	3.21	3.88	3.19
Volume* (cm^3 STP)	0.05	0.06	0.06	0.07	0.05	0.03	0.01

*These volumes correspond to the following average weight % of atoms: $H = 10.0\%$, $C = 28.1\%$, $N = 2.5\%$, $O = 59.2\%$ and $Ar = 0.2\%$.

The several natural diamonds, both type I and type II from Arkansas, USA used, gave relatively consistent results. Analytical data from a typical experiment on a type I diamond are given in Table 1. The gases released from the diamond, in decreasing order of abundance, were CO, H_2, H_2O, CO_2, N_2, CH_4 and Ar. The average atomic weight % is $O = 59.2$, $C = 28.1\%$, $H = 10\%$, $N = 2.5\%$ and $Ar = 0.2\%$. These data are consistent with the gases released by the crushing of numerous other diamonds *in vacuo*[3,4].

To determine the amount of contamination derived from the apparatus, two different approaches were used: first, control experiments with no diamonds present were carried out to determine the amount of gas released from the apparatus and second several diamond crystals were converted to graphite at lower temperatures using platinum–rhodium filaments. These experiments showed that the maximum level of contamination for nitrogen was $< 0.1\%$ and that for other gases $< 1\%$.

Since Kaiser and Bond[3] used graphite in their experiments, we conducted a control experiment with graphite. Gas release from a preconditioned sample of spectrographic grade of graphite at 2,000 °C showed nitrogen to be the major component.

Nightglow and a new band system in molecular oxygen

I PROPOSE here that the transition $^3\Sigma^+_u \rightarrow {}^1\Delta_g$ in O_2 is responsible for previously unidentified features in the nightglow from the Earth's atmosphere, and in observations of radiation emitted from recombining atomic oxygen in the laboratory. The transition violates the approximate selection rules $\Delta S = 0$ and $\Delta\Lambda = 0$, ± 1 (ref. 1); it may be compared with the transition $^1\Delta_g \rightarrow {}^3\Sigma^-_g$, which, in addition to violating these selection rules, also violates the rigorous selection rule $g \leftarrow/\rightarrow g$ for electric dipole radiation, and so proceeds by magnetic dipole radiation[2]. The transition $^3\Sigma^+_u \rightarrow {}^1\Delta_g$ may therefore be significantly stronger than the transition $^1\Delta_g \rightarrow {}^3\Sigma^-_g$.

An accurate calculation of the wavelengths of the origins of the various bands of the $^3\Sigma^+_u \rightarrow {}^1\Delta_g$ system is not possible, since only the lowest two vibrational levels of the free $^1\Delta_g$ mole-

cule have been observed. In Table 1 we present a Deslandres array based on data given by Krupenie[3]. The entries underlined correspond to features which are clearly present in published nightglow spectra[4-7]. In particular the unexplained features pointed out by Chamberlain[4] and Hennes[6] are accounted for. The bands fall near a Condon locus which corresponds closely to that found for the Herzberg I system[8] ($^3\Sigma^+_u \rightarrow {}^3\Sigma^-_g$), where the Franck–Condon factors will be similar. Other bands of the $^3\Sigma^+_u \rightarrow {}^1\Delta_g$ system may well be present in the nightglow, but are unclear because they coincide with bands of the Herzberg I system, or because they are weak. Such possible identifications are underlined with dashed lines.

As in the case of the Herzberg I system, there are a number of coincidences and near coincidences in wavelength of band origins. This arises because the vibrational quanta of the $^1\Delta_g$ state are approximately twice as large as those of the $^3\Sigma^+_u$ state. In cases where two or more bands might be present on wavelength considerations alone, comparison with bands present in the Herzberg I system[8] provides a useful guide. Thus, for example, we identify the feature at 3,789 Å (refs 4 and 6) with the (3,2) band rather than the (1,1) band, although both are predicted to have an origin at 3,786 Å. Also, preferential population of the upper vibrational levels of $^3\Sigma^+_u$ is characteristic of the nightglow[9]. It is possible that emission from lower vibrational levels of $^3\Sigma^+_u$ to $^1\Delta_g$ is present in the nightglow, and contributes to the weakly banded blue pseudocontinuum[9], but identification is not possible.

Laboratory investigations of the radiation emitted by recombination of atomic oxygen[10] have shown the presence of numerous features between 3,500 Å and 5,000 Å which do not belong to the Herzberg I system. Degen[11] has presented a high resolution spectrum of a band with its origin near 4,007 Å, and stated that most of the other unidentified bands seem to belong to this system. The rotational structure is complicated,

Table 1 Calculated band origins in Å for the system $^3\Sigma^+_u \rightarrow {}^1\Delta_g$ in O_2

v'' / v'	0	1	2	3	4	5
0	3,687	3,900	4,135	4,395	4,685	5,008
1	3,584	3,786	4,007	4,251	4,521	4,822
2	3,491	3,682	3,891	4,120	4,374	4,655
3	3,407	3,588	3,786	4,003	4,242	4,506
4	3,330	3,503	3,692	3,898	4,124	4,373
5	3,261	3,427	3,607	3,803	4,018	4,254
6	3,199	3,359	3,531	3,719	3,925	4,150
7	3,144	3,298	3,464	3,645	3,842	4,057

Entries fully underlined seem definitely present in the nightglow; those partially underlined are probably present. Entries for $v' > 7$ are omitted because these levels of $^3\Sigma^+_u$ are believed to be absent in the upper atmosphere at night.

as is to be expected for the $^3\Sigma^+_u \rightarrow {}^1\Delta_g$ system, which, like the $^1\Delta_g \rightarrow {}^3\Sigma_g$ system, will have nine branches, three Q-form, two P-form, two R-form, one O-form, and one S-form (ref. 1). In general the calculated band origins in Table 1 are a few Å less than the band positions observed in the nightglow and in the laboratory. Thus we identify Degen's band at 4,007 Å with the (3,3) band. This may be partly because the bands are red degraded, and the levels corresponding to $J = 0$ and 1 in $^1\Delta_g$ are missing, and partly because the vibrational terms for $v > 1$ in $^1\Delta_g$ need revising. A successful analysis of the rotational structure observed by Degen in terms of the transition $^3\Sigma^+_u \rightarrow {}^1\Delta_g$ would not only confirm this identification but also give accurate values for the higher vibrational terms of $^1\Delta_g$. The hypothesis presented here seems superior to the proposal of Chamberlain[12] that some of these features are due to the $^3\Delta_u \rightarrow {}^1\Delta_g$ transition in O_2; not only do the wavelengths seem to agree better, but the $^3\Sigma^+_u$ state is already known to be present in laboratory systems and in the upper atmosphere at night. The contribution of either process to the population of the $^1\Delta_g$ state observed in the nightglow will be negligible.

I thank Dr M. Gadsden for comments.

Imagery, affective arousal and memory consolidation

A DISPARITY exists between the methods and theory that have been developed to study human memory and those used in animal learning studies. Present research strategies in human memory focus on (1) differences in the stimuli-to-be stored in memory (such as the extent to which words can be encoded)[1]; (2) conditions that precede new learning which influence the acquisition, stimulus transformation and encoding of input; (3) the context in which information is presented at the time of storage or retrieval from memory (where context determines the specific encoding strategy used to store and retrieve information)[2]; and (4) conditions that affect storage decay (such as those which might prevent rehearsal or precipitate "unlearning" of information stored in memory). The main theme of this research stresses

stimulus characteristics, often causally defined, as determinants of input–output relationships in memory. Few attempts have been made to develop the structural detail of human memory with respect to underlying biological mechanisms.

Studies of biological determinants and mechanisms of learning and memory have generally been on animals and have focused on neurochemical and neurophysiological conditions that alter learning or retrieval. Unlike human learning studies, these have involved physiological manipulations of brain after learning has taken place, at a time when experience is thought to be consolidated in memory. This research and its developing theory have emphasised the role of time- and intensity-dependent, specific and non-specific, brain state arousal in memory consolidation[3]. Unfortunately, few bridges exist between the methods and theory used in the biologically oriented animal learning studies and those thought useful in researching human learning. In this study we have attempted to integrate these two territories of findings and theory through manipulations of stimulus imagery and consequent encodability and of arousal using measures which in separate studies and approaches reliably affect recall probability.

Forty college students were first practised and then individually tested in a control condition and one of four experimental conditions. In the control conditon, subjects viewed eight different groups of four common English words, each group consisting of two easily and vividly imageable words and two words difficult to image[1]. After viewing each word group for 4 s, subjects were asked to produce a single representative word which would serve to integrate each cluster of four words and to rehearse, or think about, the to-be-remembered words, for 10 s. After the subjects had seen and rehearsed all of the 32 words, they were engaged in a non-verbal distracting task for 10 min and then attempted to recall the presented words.

Different groups of these same subjects, ten in each, were also tested under one of four experimental conditions, constituting an imagery mnemonic and/or affective arousal manipulation superimposed on the control procedure. In all of these experimental conditions, subjects were provided with pictures projected from slides which were designed to help them organise input and aid recall. Pictorial stimuli depicted common human interactive themes, and were standard but ambiguous stimuli with known response characteristics [Thematic Apperception Test (TAT) plates 1, 3BM, 4, 5, 6BM, 7, 11, 13MF] which are used clinically to elicit emotionally rich themes as a projective personality test. In two of the conditions, these stimuli were presented for 10 s before the 4-s presentation of each cluster of four to-be-remembered words. The two remaining conditions involved presenting word clusters first (4 s) followed by the 10-s exposure of these same TAT slides during the time that to-be-remembered words were being rehearsed in immediate memory. Finally, one of each of the above two groups viewed the TAT slides under an instructional set to "get

Table 1 Free recall of words as a function of the timing of imagery mnemonics and affective arousal experiment conditions

		T_1	T_2	T_1A	T_2A

Change in recall produced by experimental conditions compared with control performance	HI	1.6±0.7	0.5±0.9	1.0±0.8	3.7±1.3
	LI	1.3±0.6	1.0±0.8	1.2±1.0	3.8±0.9

Subjects were studied in the following conditions: a control involving word recall without the use of imagery mnemonics or affective arousal; four experimental conditions, two involving only the use of an imagery mnemonic before the presentation of to-be-remembered word clusters (T_1) or after the presentation of these four-word sets (T_2) and the remaining two conditions using the imagery mnemonic with the induction of affective involvement before the presentation of each word cluster, (T_1A) or after their presentation, during rehearsal (T_2A). HI, High imagery words; LI, low imagery words; W/C, average number of words per recalled cluster.

involved with the projected interpersonal theme, by thinking about your own personal, relevant experiences". This manipulated set had been pretested in an independent group of 20 subjects and was shown to produce significantly higher self-ratings along a continuous global scale[4] of affective involvement compared to a set of eight non-projective test stimuli. These subjective ratings were also significantly greater than those produced in response to a content-equivalent set of conditions in which no such instructional set was introduced. At the same time, these two sets of stimuli produced the same ratings on a global imagery scale used to measure the effectiveness of the stimuli as an imagery mnemonic.

The contrasting effects of these conditions on components of recall were examined by means of a series of ANOVA. Results are displayed in Table 1 which describes changes in: (1) recall of high compared with low imagery words; (2) total recall of words; (3) the number of words per cluster that could be recalled (a measure reflecting within group structure or salience where words per cluster measures different memory processes than are involved in accessing a higher order memory unit, cluster recall[2]). The number of clusters of presented information recalled, where at least one item from that cluster was remembered, is a measure that reflects retrieval of higher order memory units and access to these structures stored in memory[2]. The number of groups of words recalled is the quotient of total word recall and word per cluster recall.

Analysis of variance demonstrated the following patterns of statistically significant effects. Control conditions consistently produced lower total recall scores than the experimental conditions, an effect due to fewer clusters of words recalled rather than differences in words per recalled clusters ($F=9.62$; d.f.$=4$, 45; $P<0.01$). In all conditions, more high imagery than low imagery words were recalled ($F=7.63$; d.f.$=1$, 45; $P<0.01$). Apparently the use of the imagery mnemonic made both high and low imagery words more accessible in memory. Imagery seemed always to change the salience of the stored stimulus trace.

Affective arousal strongly facilitated recall when information was already in memory, during a period of rehearsal and consolidation ($F=8.14$, d.f. 3, 27; $P<0.01$). Affective arousal was not effective at the time of information storage itself. Post-storage arousal facilitated recall, but increased not the number of higher order memory units (clusters) which could be retrieved but the number of words recalled per cluster (intrastructure salience).

Generally, treatments used in typical human memory studies are effective in inducing changes in the recall of higher order memory units but have little effect on recall of elements within such structure. In spite of the changes in recall produced by imagery and post-storage arousal, retrieval strategies for accessing memory were not altered. For example, neither input serial position effects on recall were altered by any of the manipulations used here, nor was output sequencing or clustering, or the tendency to maintain the integrity of higher order memory units at time of retrieval, altered in control or experimental conditions.

Our findings on the effect of arousal on memory consolidation are consistent with those in animal studies in which arousal by foot shock or drugs after learning alters trace consolidation[3], and also with findings in some clinical studies where patients with disturbances in affect, for example, depression, show disturbances in the consolidation phase of memory which is reversible by drugs that alter affect and arousal (for example, L-dopa which influences the dopamine system in brain)[5,6]. These findings and the experimental design that was used to test effects of the timing of the imagery mnemonic in association with affective arousal also points out the value of bridging the methods and theories common to traditional human memory studies, with their emphasis on storage effects, and

the relatively greater focus on post-learning variables commonly used in biologically oriented animal learning studies.

Antagonism between visual channels for pattern and movement?

GEORGESON has reported[1] some ingenious psychophysical experiments designed to test the hypothesis that 'sustained' visual cortical cells sensitive to the orientation of contours are antagonistically coupled to 'transient' cells in the same cortical column sensitive to movement at right angles to those contours. After inspecting one or other, or both, of two counter-rotating dot patterns, his subjects reported seeing "complex patterns of radial lines or curves". These appeared either to rotate in the opposite sense to the stimulus, or to be stationary if both counter-rotating disks had been viewed simultaneously in superposition. Georgeson attributed their appearance to the rebound response of 'pattern channels' inhibited during stimulation by 'motion channels' of the kind presumed to be responsible for movement after effects (MAE). We have tested this conclusion by extending the range of stimulus velocities well above and below those used by Georgeson. Our results suggest that stimulation of motion channels is not necessary for the effect observed, so that its appearance in his tests does not confirm his hypothesis.

Our doubts arose because at the speed used by Georgeson (66 r.p.m.) the retinal image of his rotating dot patterns must have generated appreciable circumferential streaks; and these alone could be expected to give rise to a 'complementary image' of radial streamers[2,3,5] without invoking stimulus movement as such. This point was first recognised by Wilson[5], who in fact described the same phenomenon in the late 1950s, together with the method of using two counter-rotating textured fields as the inducing stimulus. He listed the following after effects as the speed of rotation of the superimposed fields was increased: "(1) A set of faint, fine concentric circles were observed. (2) These became fewer but stronger and broader. (3) They expanded even more, radial whiskers became visible on the outer circles, and a general impression of flicker was observed. (4) The circles were then seen to be entirely composed of fine radial 'whiskers' or 'sparks' and appeared to pulsate in diameter. (5) With further increase of speed the circles expanded (leaving) radii, or sometimes a lattice pattern of opposite spirals, filling the whole field."

Wilson noted that the induction of orthogonal after images by rapidly moving stimuli had been described in 1845 by Sir David Brewster[6], who observed it after staring from a moving railway carriage. (Wohlgemuth, in his classical monograph *On the aftereffect of seen movement*[4], tried to explain Brewster's statement that the after effect was "transverse" to the direction of the objective movement
Fig. 1 *a*, Dot pattern used for counter-rotating stimuli; *b*, result of rotating *a* through 10° during exposure, and superposing mirror image; *c*, as *b* but 40° rotation; *d*, concentric-circle figure which excites a petalloid complementary image (see text).

as "possibly due to his changing the position of his head when he closed his eyes"!) Wilson later reported[7] that similar radial 'whiskers' can be induced by stroboscopic illumination of a single stationary circular contour.

Georgeson indicated that the 'movement analysers' he had in mind are those responsible for the familiar motion after effect or 'waterfall illusion'. Since the optimal rotation rate to generate a normal MAE is much lower than 66 r.p.m., human movement-sensitive channels should be more strongly stimulated if lower speeds were used. If Georgeson's interpretation were correct, this should intensify the radial lines seen as an after effect, and these might be expected to persist down to speeds at which the normal MAE disappears. Conversely, they should disappear at speeds above the upper threshold for perception of motion. If, however, radial lines were produced by the same mechanism as the normal complementary after image induced by inspection of stationary circular arcs (that is, by activation of contour-sensitive channels), they should persist at high rates of rotation, but disappear for rates that are too

low to produce significant circumferential streaks even though adequate for the normal MAE. We have therefore repeated Georgeson's observations, with eight subjects in all, using rates of stimulus rotation from 960 r.p.m. down to 3 r.p.m.

Our subjects viewed from 2.6 m a white screen on which two counter-rotating random-dot patterns were thrown from a 300-W projector having a motor-driven slide rotator. The two concentric images, produced with the aid of a Dove prism in front of the projector lens, were matched for brightness (110 cd m⁻² on white parts). They subtended an angle of approximately 20° at the subject's eyes, and were centrally fixated.

After an exposure of 1 min the subject immediately inspected a uniform white surface (70 cd m⁻²) and was asked to report any after images. For stimuli rotating at 60 r.p.m., all our subjects confirmed Georgeson's report of near-radial lines, usually adding that these seemed to "shimmer" or "stream" radially. Most subjects saw them extend almost to the centre, with only the central 4° clear of lines.

With a stimulus rotating at 30 r.p.m., however, six of seven subjects reported that the lines came only "about halfway in", leaving an 8° central area clear of radial lines. At 10 r.p.m. (which gave powerful MAEs with a single disk) only two of six subjects saw an after image of "faint radial whiskers" near the periphery of the stimulated field. At 6 r.p.m. all of seven subjects reported the whole test field free of radial lines, with only faint pulsating concentric rings as an after image, except that one subject (VM) detected faint radial "whiskers" around the periphery. Finally, three subjects tested at 3 r.p.m. could see no radial lines; yet the MAE at this rate (for a single disk) was still powerful over the whole area. As might be expected, the exact cutoff point for the radial after effect varies with individuals and with the rotating pattern used; but the trend of these results is clearly opposite to that predictable on Georgeson's interpretation.

Increasing the speed above Georgeson's rate of 66 r.p.m., we found no noticeable reduction in intensity of the chrysanthemum-like complementary after image up to 240 r.p.m. At 480 r.p.m. and 960 r.p.m., all observers agreed that it was considerably weaker, although still detectable; but at these speeds, the streaks produced by individual dots would be expected, and were observed, to run into each other and reduce effective contrast.

A rough quantitative check on this point can be gained by calculating the patterns of streaks to be expected if each retinal ganglion cell fired for 60 ms in response to a briefly flashed spot[8]. During this time at 60 r.p.m. each dot of a rotating pattern would trace an arc of about 20°. Figure 1a shows the dot pattern we used, and Fig. 1b and c the results of rotating it through 10° and 40° during photographic exposure and then superposing the mirror image, to simulate the streaks produced by counter-rotating fields at rates of 30 and 120 r.p.m. on the foregoing assumption. It is clear that (1) overlapping of streaks at these rates does not prevent a strongly circular pattern from developing; (2) at rates below 30 r.p.m. a progressively larger central area would become practically streak-free, and so ineffective in stimulating contour analysers; and (3) at rates above 120 r.p.m. (for our dot pattern) overlapping of streaks must progressively reduce effective contrast. This all fits quite well with the observations, and suggests that the assumed duration is of the right order of magnitude.

With a moving dot, the stimulating streak is effectively pulsed on and off as the dot passes over each receptive field, so the after effect would be expected to be (and is) stronger than that after inspecting Fig. 1b and c. Figure 1d (see ref. 2) has been included to let the reader verify that the complementary image induced by stationary concentric circles (or by a line of dots rotating at very high speed) is indeed an array of near-radial streamers. These may be seen either immediately on closing the eyes or on a uniform white surface. (At repetition rates of the order of 5–10 s⁻¹, radial streamers can be seen continuously during inspection. (Compare ref. 3, page 344.)

We conclude that Wilson's radial after effect is most parsimoniously attributed to stimulation of contour analysers by the rotating dots, and that stimulation of the motion analysers responsible for the MAE is not essential. This does not of course disprove the general idea of opponent coupling between 'sustained' and 'transient' cells. It was shown[2] that similar complementary images can be made visible continuously (not only as an after effect) by optically superimposing dynamic visual noise (for example, from a detuned TV receiver) on the fields of near-parallel contours, such at Fig. 1d[2,9]. The inference then suggested (before the discovery of contour-specific visual cells) was that channels sensitive to one orientation are rendered differentially hyperexcitable by 'satiation' of channels sensitive to the orthogonal orientation. Whether the mechanism was one of active mutual inhibition or of passive competition was left open by the psychophysical evidence; but in view of Wilson's finding[5] that the full effect requires the presence of about four to six near-parallel lines, and the fact that the wavelength of the sinuous illusory contours is typically about 4 times the inducing linespacing, it seems likely that network properties as well as single-unit characteristics are involved[2,3]. Georgeson's suggestion of antagonism between pattern- and motion-signalling channels is geared to the idea that removal of the parallel-line inducing pattern 'disinhibits' motion channels. The orthogonal patterns seen in dynamic noise suggest that even in the presence of the inducing lines, orthogonal channels for both pattern and motion may become hyperexcitable. In any case, we agree with Georgeson that it seems attractive to invoke excitation of motion channels in order to account for the streaming motion observed in the after effect, even if more complex relationships must be added to the picture to do justice to all the facts.

Evidence for a low upper limit of heritability of mental test performance in a national sample of twins

THE use of kinship correlations is a long established approach to the estimation of heritabilities (h^2) and component variances of human phenotypes. Among the best known studies are those using monozygotic and dizygotic twin correlations, data from which are commonly interpreted to represent a substantial heritability (that is, about 0.8) of IQ and other mental test performances (see Jensen[1] for review, and Jinks and Fulker[2] for the empirical requirements of this approach). Some doubt has been cast, however, over the empirical sufficiency of the most quoted estimates. Among the doubts are those concerning biographies of subjects, testing procedures, and problems emerging from the use of varied and inappropriate tests and from the subjects being of widely different ages[3]. More recent estimates using a version of the identical–fraternal twin comparisons (but derived from a sample in which the zygosities were unknown) have arrived at a value for h^2 not significantly different from zero[4–6]. The National Child Development Study (for details, see ref. 7), a longitudinal study of all the children in England, Scotland and Wales born in one week of March 1958, includes a nationally representative sample of twins about whom have been gathered considerable biographic, biometric, social and psychometric data (unpublished results). We have used this sample to investigate the broad heritability of performance on a general mental ability test.

Zygosities of twins were established during an interview of parents of twins by health visitors at the 7-yr follow-up and from responses to a letter sent to parents at the time of the

11-yr follow-up; they were asked if the twins were 'identical' or 'non-identical' that is, 'fraternal'. This does not, of course, provide conclusive evidence of zygosity; however, several studies have shown that simple questionnaire responses of this sort reach at least 95% agreement with serological criteria, and it is generally felt that misclassifications by this method are uncommon[8-10]. The proportions of identical and fraternal twins classified in this way in the present sample approximate the theoretical values, and there were a few pairs, excluded from the present study, for whom the zygosities were unknown.

comparisons. The differences are 0.185 for the verbal test (that is, appreciably greater than MZ–DZss) and 0.117 for the non-verbal test. If we are correct in assuming only marginal sex bias in the test itself they probably reflect what is known as 'treatment effect', that is, inflation of the DZss correlation by virtue of parents, teachers, peers and so on treating same-sex twins in a similar way. Identical twins, as well as necessarily being of the same sex, also look alike and have other characteristics in common. Not surprisingly, it has repeatedly been demonstrated that identical twins are generally subject to more

Table 2 Analysis of variance tables for verbal and non-verbal test scores

| | MZ n = 41 pairs | | DZ$_{ss}$ n = 55 pairs | | DZ$_{os}$ n = 40 pairs | | DZ$_t$ n = 95 pairs | |
	V	NV	V	NV	V	NV	V	NV
MS within pairs	12.207	7.335	13.118	9.773	22.569	16.569	17.097	12.634
MS between pairs	69.446	54.296	64.019	39.552	63.255	47.999	65.705	49.573
Intraclass correlation	0.701	0.762	0.659	0.604	0.474	0.487	0.587	0.594

The data considered here relate to the second follow-up study when the subjects were 11 yr old. At that time all the subjects were administered a timed (30-min), group test of general mental ability by their teachers in schools, following strict but simple instructions concerning timing and test circumstances. The test, comprising 80 alternate verbal and non-verbal items, was specially designed for survey work with children of this age group by the National Foundation for Educational Research (for further details of reliabilities and validities, see ref. 11). Although it has not been cross validated with better known standardised tests, the two sets of items comprising it would seem to be very similar to types used in typical IQ tests (Fig. 1). It is as well to draw attention to this because reported h^2 estimates for performance on scholastic attainment tests are often appreciably lower than those for general ability tests, although they vary widely depending on the precise nature of the test[12]. Because of this we have calculated separate correlations for the verbal and non-verbal performances.

Table 1 shows the mean scores and standard deviations for the whole cohort and for twins separated by zygosity and sex. (Suffixes ss and os signify same sex and opposite sex, respectively.) Overall these figures suggest a marginally better performance for girls relative to boys, including those in the dizygotic (DZ) groups. This may be due to a sex bias in the test, the main consequence of which would be to reduce the DZos correlations slightly. Table 2 contains analysis of variance tables for verbal and non-verbal scores of twin pairs. A major question is the magnitude and statistical significance of difference between correlations. The most important ones from the point of view of heritability are (monozygotic) MZ–DZss. These are 0.042 for verbal scores and 0.158 for non-verbal scores, neither of which is statistically significant. Such non-significant differences are in themselves supportive evidence for very low or zero heritabilities.

The differences between fraternal twins of the same and opposite sex (DZss–DZos) are interesting because they suggest a possible source of error in identical–fraternal twin

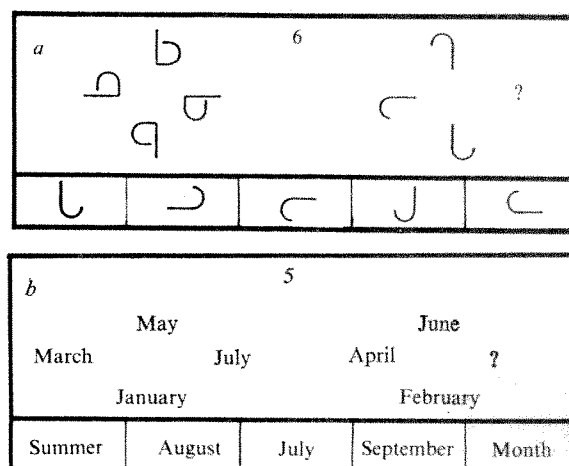
uniform treatment than fraternals[5,6]. It is therefore possible to invoke treatment effects as the basis for inflated MZ twin correlations.

Table 2 indeed illustrates what happens when these 'treatment effects' are incorporated into the estimation of heritability (t indicates the total obtained from both os and ss twins). The difference MZ–DZt is non-significant for the verbal test, but although remaining small, becomes significant for the non-verbal test; using Z scores we have

$$Z_{MZ} = 1.000; \quad Z_{DZt} = 0.683$$

$$\frac{\Delta Z(MZ - DZt)}{\sigma(Z_{MZ} - Z_{DZt})} = \frac{0.317}{0.190} = 1.668 \, (P < 0.05)$$

On the face of it these data yield a heritability of 0.336±0.189

Fig. 1 Examples of (a) non-verbal and (b) verbal items used in the mental ability test.


for non-verbal mental ability. This is obtained from the general expression, $h^2 = (r_{MZ} - r_{DZ})/(\rho_{MZ} - \rho_{DZ})$, where ρ_{MZ} and ρ_{DZ} are the theoretical correlations for identical and fraternal twins, respectively; essentially the derivation of Jensen[12]. Taking $\rho_{DZ} = 0.5$, of course, assumes no assortative mating (the presence of which would increase h^2) and no dominance or epistasis (which would decrease h^2). The magnitude of these influences is difficult to assess with accuracy from existing empirical data, but it is usually assumed that they are very small. Nonetheless, adopting Jensens'[12] estimate of $\rho_{DZ} = 0.55$ under assortative mating, and thus the maximum feasible correction to the above h^2, only increases it to 0.373. This h^2 is the consequence of introducing the usually unsuspected 'treatment effects' into the data and is at best an upper limit. It has been demonstrated that taking only minimal account of such effects in the data of previous studies reduces the reported h^2 estimates to values not significantly different from zero[5,6].

In conclusion, our nationally representative sample of twins of uniform age and test subjection, offer supportive evidence for zero or low upper limit heritabilities of mental test performance. Such estimates are considerably lower than the value of 0.8 normally quoted in psychometric research[13] and which has permeated the psychological literature. Although it is necessary to be clear about the often-inflated significance of heritability estimates[14], the present results are perhaps further indicative of the stringencies of sampling required in such studies[3].

We thank Professor Neville Butler for encouragement; Dr Joseph Schwartz, Dr Michael Schwartz and colleagues of the National Children's Bureau for comments; and the DES, DHSS and SSRC for support.

Correction to Fisher's correlations between relatives and environmental effects

FISHER[1] has given a now much used model of assortative mating, and using formulae obtained for it he analysed data[2] on human height, span and forearm. In his model, phenotypic variance is regarded as the sum of three variances, additive, dominance and environmental; and genetic variance is the sum of the additive and dominance components. This was Fisher's first important contribution to genetics and it would seem that he did not appreciate fully the implications of his model. His formulae for parent–child correlation and sib correlation, in the presence of assortative mating, are not correct for his model. Moreover, the correct formulae for these correlations for his model suggest a different interpretation when the value for (genetic/phenotypic variance) is greater than 1. I present here a summary of criticisms of Fisher's formulae; details of which, with derivation of correct formulae will be presented elsewhere.

The additive variance is obtained by fitting a linear regression on the gene content of the genotype; dominance variance is the residual genetic variance, that is, genetic, additive variance. Fisher found that the value of his symbol c_1 defined as (genetic variance/phenotypic variance) was greater than 1 for height and span and concluded that this "gives no support to the supposition that there is any cause of variance in these growth features other than genetic differences". His method of partitioning the phenotypic variance into additive, dominance and other components has recently been used for IQ and estimates of its heritability (additive variance/phenotypic variance) have been the subject of some controversy.

Fisher realised that assortative mating will cause association between genotypes ("phases of factors" in Fisher's terminology). He devised a complicated method to take account of it and found that this association increases the genetic variance of the population. The increase in genetic variance is attributable entirely to an increase in the additive variance of the population[3].

Fisher did not consider what effect assortative mating has on the genotypes of a parent and his progeny. He assumed that the additive deviations are the only cause of resemblance between parent and child as he says, "Hence, since there is no association except of z (additive values) between parent and child, the parental correlation coefficient is

$$c_1 c_2 \frac{1 \times \mu}{2}$$

Here μ is the phenotypic correlation between husband and wife and c_2 is the total additive variance/genotypic variance; c_1 has already been defined.

Wright[4] on the other hand says that "Assortative mating introduces a correlation between dominance deviations of parents and offspring and between dominance deviations of either and additive deviations of the other". Fisher did not investigate such correlations and took no account of them. It can be shown that in Fisher's model of assortative mating there is a small correlation between the additive and dominance deviations of parent and child. Thus, the assumption on which Fisher obtained his formula for parent–child correlation is not correct.

To obtain his formula for sib correlation, Fisher discarded his model of assortative mating and reverted to random mating. He said, "The variance of a sibship, for example, depends, apart from environment, only on the number of factors in which the parents are heterozygous, and since the proportion of heterozygotes is only diminished by a quantity of the second order, the mean variance of the sibships must be taken for our purposes to have the value appropriate to random mating. . . .".

It is true that the variance of single sibship will be the same under random mating and assortative mating. The proportions of different types of matings will, however, be different under the two systems. As the mean sibship variance is Σ(frequency × sibship variance), it will not be the same under the two systems.

Moreover, Fisher adds the whole of the increase in variance, $A\tau^2/(1 - A)$ where A is the genetic correlation between husband and wife and τ^2 is the additive variance appropriate to random mating, to sib covariance and no part of the increase to sib variance. This is difficult to justify assuming Mendelian segregation on which his model is based.

Consider now his two formulae together

$$\text{Parent–child correlation} = \tfrac{1}{2} c_1 c_2 (1 + \mu)$$
$$\text{Sib correlation} = \tfrac{1}{4} c_1 (1 + c_2 + 2c_2 A)$$

In the presence of dominance, the sib correlation will be greater than the parent–child correlation, therefore

$$\tfrac{1}{4} c_1 (1 + c_2 + 2c_2 A) > \tfrac{1}{2} c_1 c_2 (1 + \mu)$$

which holds only if $(1 - c_2)/2c_2 \mu > 1 - c_1 c_2$. Fisher's model of

assortative mating will hold for those values of c_1, c_2 and μ for which this inequality holds. It can be verified that it holds only for certain combinations of values of these parameters. For example, if $\mu = 0.5, c_1 = 0.8, c_2 = 0.8$, we get $0.25 > 0.36$, which is not true.

These considerations lead to the conclusion that Fisher's formulae for parent–child and sib correlations are not correct for his model. It is, however, possible to obtain formulae using Fisher's model which do not suffer from these deficiencies. These formulae, in Fisher's notation, are

Parent–child
$$\text{correlation} = \tfrac{1}{2}c_1c_2[1 + A(1 - A)^2] + \tfrac{1}{2}c_1(1 - c_2)A(1 - A)$$
$$\text{Sib correlation} = \tfrac{1}{2}c_1c_2[1 + A(1 - A)^2] + \tfrac{1}{4}c_1(1 - c_2)$$

In both, the first term represents the contribution of additive deviations to correlation and the second term the contribution of dominance deviations. Note that the contribution of the dominance deviations to parent–child correlation is smaller than their contribution to the sib correlation since $A(1 - A) \leqslant \tfrac{1}{4}$. This is another reason why the concept of heritability defined as additive variance/phenotypic variance cannot be applied to human populations mating assortatively.

If the coefficient of assortative mating μ is known, the value of c_1 and c_2 can be obtained from the parent–child and the sib correlation formulae. Effectively, the difference between the two correlations gives a fraction of the dominance variance. The formulae given here and those obtained by Fisher, however, are for genetic correlations which are unknown and phenotypic correlations have been used instead. If the environments of sibs are more alike than those of parent and child, the difference between phenotypic correlations will also contain a fraction of the environmental variance. When the phenotypic correlational difference is too large to be explained by the amount of dominance variance in the population, the value of c_1 will come out to be greater than 1. Thus, such a value, far from being evidence for no environmental effects, indicates their presence. On the other hand, a value less than 1 for c_1 does not, of itself, exclude environmental effects, which could mean that the contributions of dominance deviations, as well as of environmental effects, are small.

The work reported here was carried out at Galton Laboratory, University College, London under the supervision of Professor C. A. B. Smith, to whom I am grateful.

Effects of artificial selection on reproductive fitness in *Drosophila*

A common feature of many selection experiments, when polygenically determined traits are involved, is a reduction in the reproductive fitness of the selected strains. Experimental selection for differences in the numbers of abdominal bristles and sternopleural chaetae in *Drosophila melanogaster* produced sterility and a reduction in fertility in the selected strains[1,2]. Latter[3] found that the "competitive index" (mating propensity, female fecundity and survival ability) had fallen sharply in strains of *D. melanogaster* subjected to experimental selection for differences in scutellar bristle number. Selection in *Tribolium* for changes

in developmental rates produced alterations in productivity, body size and viability of the flour beetles[4]. The reproductive fitness of chickens under selection for increased shank length was reduced steadily throughout the selection process[5].

Lerner[6] proposed that an increase in homozygosity is directly responsible for the reduction in reproductive fitness found in selected strains. He submitted evidence suggesting that heterozygosity is of prime importance in producing a balanced, highly fit natural population. This preselection phenotype is the outcome of numerous generations on which natural selection has operated to produce maximum reproductive fitness. As experimental selection proceeds, the balanced phenotype and genotype favoured by natural selection is disrupted. The selection process favours homozygosity for those genes which influence the selected trait. Homozygosity is also increased by incidental inbreeding, a consequence of the experimental selection procedure. On relaxation of the experimental selection pressures, natural selection is free to restore a balanced phenotype. The most heterozygous individuals are again favoured, causing the "gains" made in the experimental selection scheme to be lost. Lerner has called this phenomenon genetic homoeostasis and defined it as "the property of the population to equilibrate its genetic composition and to resist sudden changes".
